Introduction: Low-dose CT screening is effective in reducing lung cancer mortality in high-risk populations. Ongoing research is focused at increasing cost effectiveness and improving risk stratification for screening. Genetic variation and exposure to ambient air pollution (AAP) are known risk factors for the development of lung cancer. However, their value in the context of risk stratification for screening remains poorly explored. In >18,000 Dutch study participants, we here assess the value of polygenic risk scores (PRSs), derived from genetic variation previously linked to lung cancer, and AAP exposure for predicting lung cancer, mortality, and actionable screening outcomes.

Methods: We evaluated the association and discriminative ability of PRSs and AAP exposure with lung cancer in a Dutch prospective population cohort, the Rotterdam Study (RS) (N=11,493, age: ≥45yrs.) and a Dutch-Belgian lung cancer screening cohort, the Nederlands-Leuvens Longkanker Screenings Onderzoek (NELSON) (N=7,394, age: 50-74yrs., persons with a history of heavy smoking). For PRS construction, we selected genome-wide association studies (GWAS) analyzing >10,000 lung cancer cases of European ancestry. We generated two weighted, restricted PRSs: PRS-McKay and PRS-Byun, consisting of 48 and 36 independent genetic variants, respectively. For the NELSON participants, we extracted annual AAP exposures to NO2, ozone, particulate matter 10 (PM10), PM2.5, and ultra-fine particles (UFP) at their residential ZIP code. All predictors were analyzed as continuous (z-standardized) and categorical variables (top and bottom deciles vs. the 40th-60th percentile). Additionally, we evaluated the relationship of the continuous PRSs and PM2.5 with screening outcomes in NELSON, i.e. lung cancer-specific and all-cause mortality, and positive/indeterminate screening-test results.

Results: PRS-Byun was associated with lung cancer and showed discrimination in RS and in NELSON (odds ratio (OR) per SD [95% CI]: 1.19 [1.07-1.32] and 1.28 [1.13-1.44], area under the curve (AUC) [95% CI]: 0.541 [0.510-0.572] and 0.569 [0.533-0.604], respectively). Moreover, we observed an association for the top decile of PRS-Byun in NELSON (OR [95% CI]: 2.35 [1.54-3.58]). PRS-McKay and only PM2.5 out of all interrogated AAP exposures also predicted lung cancer in NELSON (OR [95% CI]: 1.22 [1.08-1.37] and 1.11 [1.01-1.22], AUC [95% CI]: 0.560 [0.525-0.596] and 0.530 [0.503-0.557], respectively). In a baseline lung cancer model containing age, sex, and pack-year history, PRS-Byun and PM2.5 added 0.012 (AUC [95% CI]: 0.656 [0.620-0.691]) and 0.002 (AUC [95% CI]: 0.646 [0.610-0.682], respectively) to its discriminative power in NELSON. Both PRSs were associated with lung cancer mortality (OR PRS-McKay [95% CI]: 1.24 [1.05-1.47] and OR PRS-Byun [95% CI]: 1.24 [1.05-1.47]), but not with all-cause mortality. Only PRS-McKay was significantly associated with a positive/indeterminate screening-test result in NELSON (OR [95% CI]: 1.08 [1.02-1.15]). This association remained significant when the analysis was stratified to participants who did not develop lung cancer.

Conclusions: Our findings suggest a potential role for PRS and AAP — more specifically PM2.5 exposure — for risk stratification in lung cancer screening. PRS-Byun and PM2.5 exposure were associated with a true lung cancer diagnosis, but not with a positive/indeterminate screening-test result, highlighting that these predictors could help limit unnecessary follow-up in screening programs.

Introduction: Indoor radon (iRn) is a leading cause of lung cancer (LC) in non-smokers, and the second in smokers due to synergistic effects. Preclinical data suggest alpha radiation can influence the immune system and modulate the TME. However, the immune TME associated with iRn, with or without tobacco-smoking remains unknown. In this study, we aimed to morphologically characterize the immune-TME of NSCLC according to the exposure to iRn alone or combined with tobacco-smoking.

Methods: Prospective cross-sectional study of patients with NSCLC enrolled across 15 Spanish hospitals from Jan/21 to date. iRn was measured using alpha-track detectors. Demographics, home characteristics, and additional exposure data were collected via a detailed questionnaire. Clinical/Tumor data were prospectively recorded in an electronic case report form. Tissue blocks were optionally collected for translational research. We morphologically characterized the TME phenotype and density of tumor-infiltrating lymphocytes (TILs), assessed by LC pathologists. High-TILs was defined as >10%, and the TME classified as inflamed, desert or excluded. Immunohistochemistry (IHC) was performed in cases with available tissue.

Results: Out of 750 patients enrolled, with 357 H&E slides and tissue-blocks collected. We report here the first analysis of 298, with available clinical/tumor/exposure data. Among them 59% were male, 76% smokers, with a median age of 65. One-third had advanced-stage and adenocarcinoma was the predominant histology (61%). A total of 41% had NSCLC harbouring driver alterations, and 30% had ≥50%PD-L1 expression. Median iRn was 29 Bq/m3 (10-710). A total of 36 pts was exposed to ≥150 Bq/m^3, including 14 non-smokers and 22 smokers. Additionally, 175 pts (59%) were exposed only to tobacco-smoking, and 87 (33%) were not exposed to either iRn or tobacco-smoking. TIL-density was evaluable in 256 patients. High-TILs were observed in 121 (47%) with a median of 10% (0-85), significantly higher in smokers (15% vs. 7% in non-smokers, p=0.02) and in squamous histology (17% vs. 9% in non-squamous, p=0.021). TME was evaluable in 221 patients: 46% showed an inflamed-TME, 33% had a desert-TME, and 21% an excluded-TME. High-TILs were observed in 45% (5/11) of iRn-exposed patients vs 51% (55/108) of smoking-group, and 44% (23/52) of non-exposed group (p=0.06). This proportion increased significantly to 56% (10/18) in the combined-group (iRn+smoking) vs. others (p=0.019). TME was significantly associated with exposure. In the iRn-exposed group, an inflamed-phenotype was identified in 56% (5/11) vs. 27% with a desert-TME vs. 9% with an excluded-TME (p=0.019). An inflamed TME was also predominant in the smoking-group, 51% (52/101) vs. 27% (11/41) in the non-exposed group. In the combined-group, the inflamed-TME was present in 50% (9/18), followed by 39% as dessert and 11% excluded. Among the 5 iRn-exposed cases with inflamed-TME, IHC (4) showed highCD8$^+$/PD1$^+$expression, and CD4$^+$/FOXP3$^+$expression. In the combined-exposure group, IHC (6) showed highCD8$^+$/PD1$^+$ and CD4$^+$expression, with low-FOXP3$^+$expression.

Conclusions: In this study, we observed that exposure to radon, especially combined with tobacco-smoking, was associated with increased TIL-density and a predominance of inflamed-TME in NSCLC, suggesting a potential immunomodulatory effect. Further in-depth characterization of the TME is needed to better understand the clinical implications of radon in NSCLC.

OA01.03 Lung Cancer Among People Who Never Smoked: Global Epidemiology and Initial Identification of Early Detection Biomarkers

H. Robbins[1], H. Zahed[1], C. Bulos[1], K. Alcala[1], X. Feng[1], M. Johansson[1], f. The Lung Cancer Cohort Consortium[1]
[1]International Agency for Research on Cancer, Lyon/FR

Introduction: In some contexts, low-dose CT (LDCT) screening is being offered to people who never smoked (PWNS), though with evidence of overdiagnosis. We aimed to understand how rates of lung cancer among PWNS vary by geographical region and sex, and to identify novel biomarkers to identify PWNS at elevated risk of lung cancer.

Methods: We analyzed lung cancer risk among 1.47 million PWNS from 24 population cohorts from Europe, North America, Asia, and Australia in the Lung Cancer Cohort Consortium (LC3). Lung cancer in LC3 cohorts is typically diagnosed symptomatically, rather than by screening. We further used Olink Proteomics assays to measure 2,943 proteins in blood from 180 PWNS who developed lung cancer within 5 years after blood draw and 180 PWNS controls matched on study, age, and date of blood draw.

Results: Compared with cohort participants from North America, lung cancer incidence among PWNS was higher in those from East/Southeast Asia (HR=2.20, 95%CI=2.08-2.33) and lower in those from Europe (HR=0.64, 95%CI 0.60-0.68) and Australia (HR=0.65, 95%CI=0.55-0.77). Lifetime risk of lung cancer among PWNS to age 75 years was similar between males and females in each region, including among East/Southeast Asian PWNS (East/Southeast Asian females=2.1%, 95%CI=1.8-2.4%, East/Southeast Asian males=1.8%, 95%CI=1.3%-2.5%, with lifetime risks in North America, Europe, and Australia ranging from 0.5%-0.9%). Among PWNS in the USA, compared with Whites, lung cancer risk was higher among Black PWNS (HR=1.23, 95%CI 1.08-1.41) and Asian-American PWNS (HR=1.34, 95%CI=1.12-1.61) but similar among Hispanic PWNS (HR=0.94, 95%CI=0.74-1.18). We identified 2 proteins associated with future lung cancer risk among PWNS after correcting for multiple comparisons: CEACAM5 (OR=1.65 for a 1-SD increase, 95%CI=1.31-2.09) and CEACAM6 (OR=1.72, 95%CI=1.33-2.22). These associations replicated successfully among participants from UK Biobank.

Conclusions: Risk of lung cancer among people who never smoked is higher among East/Southeast Asians compared with other world regions but appears similar between males and females across 4 continents. Planned research in the LC3 will increase the sample size for protein biomarker discovery and validation for lung cancer in PWNS.

Figure 1. Incidence and lifetime risk of lung cancer among 1.4 million Lung Cancer Cohort Consortium participants who never smoked, by world region.

OA01.04 Investigating the Association Between Procedure Duration of Coronary Angiography and Intervention and Postoperative Cancer Risk

[1]Department of Respiratory and Critical Care Medicine, the Affiliated Qingyuan Hospital (Qingyuan People's), Guangzhou/CN ,[2]Department of Respiratory and Critical Care Medicine, the Affiliated Qingyuan Hospital (Qingyuan People's Hospital),, Qingyuan/CN

Introduction: Coronary angiography (CAG) and percutaneous coronary intervention (PCI) have long been cornerstones in treating coronary artery disease. These procedures are well-established in improving both clinical outcomes and quality of life. However, with their increasing use, especially under prolonged exposure settings, questions have emerged regarding the long-term oncologic risks potentially tied to cumulative low-dose ionizing radiation during such interventions.This study investigates whether the length of CAG/PCI procedures correlates with the incidence of post-interventional cancer, aiming to inform future strategies for oncologic risk assessment in patients undergoing coronary interventions.

Methods: We conducted a retrospective analysis of 1,079 patients who underwent their first CAG or PCI at our institution between January 2012 and March 2022. Using a 35-minute threshold—based on the median duration—we stratified patients into two groups: longer (≥35 min) and shorter (<35 min) procedure times. To control for baseline imbalances, propensity score matching (PSM) was implemented. Following PSM, we applied a suite of variable selection methods, including univariate logistic regression, stepwise regression, LASSO, ridge regression, and elastic net models. Significant predictors were included in a multivariable logistic regression framework. Cancer-free survival was examined via Kaplan-Meier curves, and subgroup analyses were conducted by cancer type. Sensitivity analyses before and after matching further supported model robustness.

Results: Post-matching, both groups contained 470 individuals with well-balanced covariates (SMD <0.1, all p-values >0.05). The multivariable model identified age ≥66 years (OR=2.40, p=0.003), tobacco use history (OR=2.58, p=0.040), hypertension (OR=2.64, p<0.001), elevated systemic immune-inflammation index (SII ≥460, OR=2.22, p=0.006), reduced left ventricular ejection fraction (LVEF <54%, OR=1.96, p=0.019), and prolonged procedure time (OR=2.32, p=0.004) as independent predictors of cancer development. No substantial multicollinearity was observed (VIFs <5). Survival analysis revealed shorter cancer-free intervals in the longer-duration group (log-rank p=0.006), a finding further supported by adjusted Cox regression. Notably, subgroup analysis highlighted a specific association between longer procedure time and increased lung cancer risk (OR=2.90, p=0.029), whereas other cancer types showed no significant relationships.

Conclusions: Longer durations of CAG or PCI (≥35 minutes) appear to independently increase the risk of developing cancer after the procedure, with lung cancer showing the strongest association. These findings suggest that procedure time could serve as a practical indicator in post-interventional oncology risk models. For high-risk populations, more rigorous follow-up and tailored cancer surveillance may be warranted. Prospective, large-scale investigations will be essential to confirm these results and clarify the biological underpinnings linking procedural exposure to oncogenesis.

Introduction: The SKYSCRAPER-05, phase II, open-label, multicenter study (NCT04832854) assessed neoadjuvant and adjuvant treatment with tiragolumab, an anti-TIGIT antibody, plus atezolizumab with/without platinum-based chemotherapy, in locally advanced resectable NSCLC.

Methods: Eligible patients (previously untreated; Stage II-IIIB [AJCC V8], locally advanced resectable NSCLC) were enrolled in Cohort A (PD-L1 ≥50%; per SP263 assay) or Cohort B (PD-L1 any). Cohort A received neoadjuvant tiragolumab (600mg IV) plus atezolizumab (1200mg IV) Q3W (4 cycles), followed by surgery and investigator's choice of adjuvant tiragolumab plus atezolizumab Q3W (16 cycles) or adjuvant platinum-based chemotherapy (4 cycles). Cohort B received neoadjuvant tiragolumab (600mg IV) plus atezolizumab (1200mg IV) Q3W plus chemotherapy (4 cycles), followed by surgery and adjuvant tiragolumab plus atezolizumab Q3W (16 cycles). Primary endpoints: major pathological response (MPR), surgical feasibility and safety. Secondary endpoints: pathological complete response (pCR) and event-free survival (EFS).

Results: At clinical cut-off (14 Feb 2024), 50 patients were enrolled (Cohort A, n=8; Cohort B, n=42). Most patients were male (70%) and white (66%); in Cohort B, 57%, 24% and 19% of patients had tumors that were PD-L1 <1%, 1-49% and ≥50%, respectively. The efficacy and safety evaluable populations comprised 48 patients who received ≥1 dose of study treatment (Cohort A, n=7; Cohort B, n=41; median follow-up 9.5 months). Cohort A was terminated early due to the evolving treatment landscape. Overall, 96% of patients received a resection, of whom 4% had a pneumonectomy and 90% a lobectomy/bilobectomy; 96% of patients had an R0 resection. In Cohort B, the MPR rate was 51% (95% CI: 35-67) and the pCR rate was 29% (95% CI: 17-46); patients achieved MPR and pCR across all PD-L1 subgroups (Table). EFS was immature. In Cohort B, two patients (5%) experienced surgical delays due to adverse events (AEs), and two patients (5%) did not undergo surgery due to progressive disease (Table). Grade 3-5 treatment-related AEs occurred in two (29%) and 17 (41%) patients in Cohorts A and B, respectively; Grade 3-5 surgery-related AEs occurred in one (14%) and two (5%) patients, respectively (Table). Nine patients (22%) in Cohort B (zero in Cohort A) experienced AEs leading to treatment withdrawal.

Conclusions: In the SKYSCRAPER-05 study in locally advanced resectable NSCLC, neoadjuvant and adjuvant tiragolumab plus atezolizumab with/without chemotherapy was surgically feasible, and demonstrated a safety profile consistent with expectations and MPR rates across PD-L1 subgroups similar to other perioperative immunotherapy plus chemotherapy regimens.

Introduction: Neoadjuvant osimertinib±chemotherapy demonstrated statistically significant improvements in major pathological response (MPR) rates vs placebo+chemotherapy in patients with resectable EGFRm stage II-IIIB NSCLC in the Phase 3 NeoADAURA study (NCT04351555). We report results from a pre-planned exploratory analysis using an ultra-sensitive circulating tumour (ct)DNA-based molecular residual disease (MRD) assay to predict outcomes in NeoADAURA.

Methods: Adult patients with resectable EGFRm (Ex19del/L858R) stage II-IIIB NSCLC and WHO PS ≤1 were randomised 1:1:1 to neoadjuvant osimertinib 80 mg QD (≥9 weeks) + chemotherapy (cisplatin/carboplatin+pemetrexed; 3 cycles, Q3W), osimertinib monotherapy 80 mg QD (≥9 weeks), or placebo QD (≥9 weeks) + chemotherapy (3 cycles, Q3W), followed by surgery. Baseline (cycle 1 day 1 of neoadjuvant treatment) and pre-surgical plasma samples were tested for detection of ctDNA (MRD+/MRD-) using personalised tumour-informed MRD panels (NeXT Personal®, Personalis®). Baseline and pre-surgical MRD status were compared with MPR and event-free survival (EFS). MRD clearance was defined as a 10-fold decrease in ctDNA or MRD- in the presurgical sample after baseline MRD+.

Results: Of 358 patients randomised, 210 had samples for MRD panels; 189 had evaluable MRD panels (90%; osimertinib+chemotherapy n=61, osimertinib n=64, placebo+chemotherapy n=64). At baseline, 71% of the 189 patient samples were MRD+ whereas 30% had COBAS-detected plasma EGFRm. Patients with baseline MRD- vs MRD+ had less extensive disease (stage II 81% vs 39%, stage III 19% vs 61%; median tumour size 4.1mm vs 4.3mm; mean number of positive lymph nodes 0.60 vs 1.3) and improved EFS (HR for MRD- vs MRD+, 0.24, 95% CI 0.07, 0.80). Treatment with osimertinib-containing regimens led to decreased pre-surgical vs baseline MRD+ rates (osimertinib+chemotherapy 23% vs 77%, osimertinib 23% vs 72%, placebo+chemotherapy 53% vs 68%; Table) and higher MRD clearance rates vs placebo+chemotherapy (osimertinib+chemotherapy 83%, osimertinib 84%, placebo+chemotherapy 58%; Table). Across arms, more patients with pre-surgical MRD- vs MRD+ (20% vs 9%; Table) and with MRD clearance vs non-clearance (24% vs 6%; Table) had an MPR.

Conclusions: The tumour-informed, ctDNA-based MRD assay had a greater tumour detection rate vs single EGFR gene mutation testing. Baseline MRD status was prognostic for clinical outcomes. Osimertinib-containing regimens improved pre-surgical MRD clearance vs placebo+CT; pre-surgical MRD- and clearance were associated with MPR. These findings support the potential utility of neoadjuvant osimertinib-containing regimens in patients with resectable EGFRm stage II-III NSCLC; longer follow-up will determine how MRD status may guide treatment decisions in this setting.

Introduction: Neoadjuvant nivolumab pluschemotherapy demonstrated statistically significant and clinically meaningfulimprovements in the primary endpoints of event-free survival (EFS) andpathologic complete response (pCR) inthe phase 3 CheckMate 816 study and is the sole neoadjuvant-onlyregimen to demonstrate statistically significant overall survival (OS) benefitin a phase 3 study of chemoimmunotherapy for resectable solid tumors. Here, we report final, 5-year OS by surgical outcomes fromCheckMate 816, the longest follow-up among studies evaluating neoadjuvant/perioperativechemoimmunotherapy in resectable NSCLC.

Methods: Adultswith stage IB-IIIA (per AJCC v7) resectable NSCLC, ECOG PS ≤1, and no known EGFR/ALKalterations were randomized 1:1 to receive nivolumab plus chemotherapy Q3W orchemotherapy Q3W for 3 cycles, followed by surgery within 6 weeks aftertreatment. EFS and pCR (both per blinded independent review) were primaryendpoints. OS was a key prespecified, statistically powered, hierarchicallytested secondary endpoint. Exploratory analyses included OS by definitivesurgery status, and OS and patient-reported outcomes (PROs; per the EQ-5D-3L utilityindex) by surgical approach, extent of resection, and completeness ofresection.

Results: With a median follow-up of 68.4 months (range, 59.9-85.2; database lock, January 23, 2025), continued OS benefit was seen with neoadjuvant nivolumab plus chemotherapy (n=149) versus chemotherapy (n=135) in patients with definitive surgery (median [95% CI], not reached [NR] vs 76.8 months [73.7-NR]; HR [95% CI], 0.69 [0.46-1.03]; 5-year OS rates, 74% versus 63%). Median OS (95% CI) was 32.9 months (11.0-44.1) with nivolumab plus chemotherapy (n=30) versus 22.0 months (15.6-38.3) with chemotherapy (n=44) in patients without definitive surgery (HR [95% CI], 1.04 [0.60-1.79]). OS was improved with nivolumab plus chemotherapy versus chemotherapy, regardless of surgical approach and extent of resection, and in patients with R0 resection (Table). Any-grade and grade 3-4 surgery-related adverse events occurred in 45% and 11% of patients, respectively, treated with nivolumab plus chemotherapy and in 49% and 15% of patients treated with chemotherapy. PROs by surgical approach and extent of resection will be presented.

Conclusions: In this final 5-year analysis from CheckMate 816, neoadjuvant nivolumab plus chemotherapy demonstrated long-term survival benefit versus chemotherapy in patients with resectable NSCLC who received definitive surgery, regardless of surgical approach or extent of resection and including patients with R0 resection. These findings, along with previously reported results demonstrating statistically significant OS benefit with nivolumab plus chemotherapy, further affirm the use of this regimen as a standard neoadjuvant treatment in patients with resectable NSCLC.

Table. OS by surgical outcomes in patients with definitive surgery

	Nivolumab plus chemotherapy versus chemotherapy				
	Surgical approach		Extent of resection[a]		Completeness of resection
	Minimally invasive[b]	Thoracotomy or conversion[c]	Lobectomy	Pneumonectomy	R0
n	44 vs 29	105 vs 106	115 vs 82	25 vs 34	124 vs 105
HR (95% CI)	Not calculated[d]	0.81 (0.53–1.26)	0.79 (0.48–1.31)	Not calculated[d]	0.65 (0.41–1.01)
5-year OS rate, %	89 vs 68	67 vs 62	74 vs 67	80 vs 53	75 vs 62

[a]Patients may have had ≥ 1 surgery type.
[b]Includes minimally invasive-thoracoscopic/robotic approaches.
[c]Defined as conversion from minimally invasive surgery to thoracotomy.
[d]HR was not calculated due to an insufficient number of events (< 10 per arm).

OA03.01 Multiomic Single Cell Profiling Reveals Novel Evolutionary Trajectories in Lung Carcinogenesis

H. Hong, D. Cai, C. Zhang, J-T. Zhang, L-X. Yan, H-J. Li, Y-D. Lin, B-Y. Jiang, Y-L. Wu, W-Z. Zhong
Guangdong Provincial People's Hospital, Guangzhou/CN

Introduction: Multiple early-stage lung cancer (MPLC) is increasingly being detected owing to the advancements in low-dose CT screening. However, the underlying molecular mechanism driving tumorigenesis remains poorly understood. This study aims to elucidate tumor evolution trajectories, focusing on the functional plasticity in histologically normal tissue, representing the earliest changes in carcinogenesis.

Methods: We performed single cell transcriptomic profiling in 88 paired paratumor and tumor samples from 16 solitary primary lung cancer (SPLC) and 18 MPLC using a multiregion sampling strategy. To delineate the field of injury, we performed single cell DNA sequencing (scDNA) to characterize tumor-associated mutation profiles in histologically normal tissue.

Results: The SPLC cohort comprised patients with single pathologically confirmed lung adenocarcinoma nodule, while the MPLC cohort included patients with 2-80 suspicious nodules with a median number of 15. We distinguished malignant cells from normal epithelial cells based on copy number variation (CNV) patterns. Normal epithelial cells were subclassified into type 1 pneumocytes (AT1), type 2 pneumocytes (AT2), intermediate cells (IC), club cells, basal cells and Epi_CXCL14 cells as well based on marker gene expressions. Intermediate cells, characterized by co-expression of AT1 and AT2 markers, were further subclassified into IC1 (IC1_NAPSA), IC2 (IC2_PLAUR) and IC3 (IC3_SPP1). Notably, IC3 cells that displayed elevated SPP1, APOC and GPNMB expression were specifically enriched in histologically normal lung tissue from MPLC patients, which is more pronounced in patients with more than 10 tumors. Intriguingly, we identified two distinct tumor development routes including a stochastic pathway and an inflammatory associated pathway. In the stochastic trajectory, AT2 cells differentiated into IC1 and could further develop into either malignant cells or AT1. In the inflammatory trajectory, AT2 cells developed into IC1, followed by IC3, and finally progressed to tumor formation, which was exclusively observed in MPLC. Functional characterization revealed an increased cellular plasticity in both IC1 and IC3, with both cells upregulating genes related to cell structure regulation. Specifically, IC3 demonstrated upregulated leukocyte mediated immunity, regulation of mitotic cell cycle and MAPK pathway activation compared to other epithelial subtypes, suggesting close association between IC3 and immune cells. Moreover, malignant cells derived from the inflammatory trajectory demonstrated elevated cytokine production, cell proliferation and myeloid migration, consistent with the charcteristics of IC3. scDNA profiling of histologically normal lung tissue revealed a prevalent clonal expansion of tumor related mutation, including GNA11, ERBB4, RET and EGFR, which is related to cell proliferation and MAPK pathway. We found an increased frequency of single-nucleotide variants and small insertions/deletions within the normal lung tissue of MPLC patients, compared to those of SPLC patients.

Conclusions: We identified two distinct evolutionary trajectories in lung carcinogenesis. The inflammation-associated trajectory mediated by IC3_SPP1 promotes MPLC development. Our findings collectively demonstrate that inflammatory remodeling facilitates tumor evolution, providing novel insights into the pathogenesis of multiple primary lung cancers and potential targets for early intervention strategies.

OA03.02 Deciphering Genomic Evolution of Metastatic Organotropism With Large-Scale Paired Primary Lung Cancers and Metastases

W-F. Tang[1], D. Xie[2], T. Jiang[3], S-L. Mo[2], H. Zhang[2], X-W. Zhai[4], Y. Liang[5], W-Z. Huang[5], H-M. Jiang[5], C. Zhang[1], Z. Hu[2], W-Z. Zhong[1]
[1]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN ,[2]Key Laboratory of Quantitative Synthetic Biology, Shenzhen Institute of Synthetic Biology, Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences, Shenzhen/CN ,[3]Department of Medical Oncology, Shanghai Pulmonary Hospital, Thoracic Cancer Institute, Tongji University School of Medicine, Shanghai/CN ,[4]MOE Key Laboratory of Gene Function and Regulation, State Key Laboratory of Biocontrol, School of Life Sciences, Sun Yat-Sen University, Guangzhou/CN ,[5]Department of Cardiothoracic Surgery, Zhongshan City People's Hospital, Zhongshan/CN

Introduction: Metastasis is the primary cause of death in lung cancer patients, yet our understanding of the genomic determinants and evolution across different metastatic sites remains limited.

Methods: We comprehensively analyzed whole-exome sequencing data from 538 paired primary and metastatic tumors from 217 non-small cell lung cancer (NSCLC) patients, including brain (BM, n=70), distant extracranial (ExM, n=56) and lymph node (LNM, n=195) metastases (Figure A). Furthermore, we retrieved 128 patients from the TRACERx 421 cohort who developed early-stage lung cancer as the non-metastatic control group (ES_P). Genomic drivers and evolutionary trajectories between different metastatic sites were explored.

Results: Overall, BMs harbored higher mutation burden than ExM (P=0.014) and LNM cohort (P=0.0016), while the mutation burden between ExM and LNM cohort were comparable. Similar patterns were observed in the corresponding paired primary tumors (Figure B). Despite the high concordance in driver genomic alterations between paired primary tumors and metastases, several driver genes (including PTPRD, FAT1, ARID1A and CDK12) were more frequently mutated in the brain-metastatic primary tumors as compared to the primary tumors of early-stage and with extracranial and lymph node metastases (Figure C). Notably, these genes were under strong positive selection in primary tumors (Figure D). Unexpectedly, we found BM experienced frequent losses of early driver mutations through specific loss of heterozygosity (LOH) (Figure E-F). This suggested that a higher level of purifying selection was also operating during the initiation of BM. Furthermore, polyclonal seeding was common in LNM (44.1%, 86 out of 195) and in ExM cohort (37.5%, 21 out of 56), but relatively rarer in BM (20%, 14 out 70), which suggested that brain metastasis underwent more stringent selection (Figure G-H).

Conclusions: Our systematic analysis revealed distinct evolutionary trajectories between BM and ExM/LNM in lung cancer, demonstrating that drivers of brain metastatic tropism were already presented in primary tumors rather than being acquired during metastatic spread. Furthermore, this study provides a compendium of candidate brain-tropism metastatic drivers for potential early prediction and intervention of this lethal disease condition.

OA03.03 Rilvegostomig Enhances Ex Vivo Immune Activation in Patient-Resected NSCLC Tumors Over PDx or PDX/aTIGIT Combination Therapy

J. Ratiu[1], P. Chariou[1], T. Connor[1], V. Roudko[2], J. Blando[1], A. Reddy[2], E. Galery[1], R.A. Halpin[1], N. Mitchell[1], J. Ren[1], K. Malhotra[1], J. Wagner[1], B. Starich[1], C. Parmar[2], C. Rands[3], V. Shankarappa[4], C. Yang[1], J. Boland[1], Y. Mazor[1], M. Cobbold[2], S. Hollingsworth[3], D. Palmer[1], S. Hammond[1], K. Pollizzi[1], D. Dinulescu[1]
[1]AstraZeneca, Gaithersburg/MD/USA ,[2]AstraZeneca, Waltham/MA/USA ,[3]AstraZeneca, Cambridge/GB ,[4]AstraZeneca, Barcelona/ES

Introduction: Rilvegostomig is a monovalent, bispecific humanized IgG1 monoclonal antibody that binds to human TIGIT and PD-1 with high affinity. Rilvegostomig was engineered with a triple-mutation in its fragment crystallizable (Fc)-domain to prevent NK/macrophage-mediated depletion of TIGIT-expressing effector cells. Rilvegostomig has shown promising anti-tumor activity in NSCLC patients in a Phase I/II clinical trial (NCT04995523) and is under investigation in multiple Phase III clinical trials (BTC: NCT06109779, NCT06467357; GC: NCT06764875; NSCLC: NCT06357533, NCT06564844, NCT06627647, NCT06692738). Here, we report the enhanced anti-tumor immune activity of rilvegostomig compared to clinically approved anti-PD-(L)1 drugs and the combinations of anti-PD-1 + anti-TIGIT mono/bivalent antibodies with Fc-active or Fc-reduced domains in a nonclinical human tumor explant model.

Methods: NSCLC tumor fragments from 68 patients were evaluated. These fragments retain the tumor cell composition and immunosuppressive factors of the tumor microenvironment (TME) to provide a physiologically relevant nonclinical model to evaluate dynamic changes in the TME after ex vivo addition of IO therapy. A portion of the tumor fragments was immediately collected post fragmentation for 'baseline' evaluation by IHC and flow cytometry. Remaining tumor fragments were cultured in medium containing therapeutic agents. After 96 hours, IFN-γ levels were quantified as a marker of ex vivo immune activity. The frequency of tumors with statistically significant changes in IFN-γ was defined in comparison with untreated controls (fold change > 1.5, $p<0.05$ determined by Wilcoxon Rank Sum Test).

Results: In a cohort of 68 NSCLC resected tumors, 46% (31/68) of the tumors demonstrated increased IFN-γ when treated with rilvegostomig, whereas, clinically approved anti-PD-1 or anti-PD-L1 monotherapies only elicited increased IFN-γ in 34% (23/68) and 7% (2/29) of the tumors, respectively. Rilvegostomig's activity was observed across PD-L1 expression levels, histological subtypes, disease stages, smoking status, and levels of CD8 immune infiltration. To evaluate the effect of the bispecific format, a subset of the tumors was treated with a combination of rilvegostomig's parental monovalent mAbs. This combination elicited IFN-γ in 41% (14/34) of the sampled tumors. Furthermore, to understand the contribution of Fc-biology in mediating an anti-TIGIT effect, a subset of the tumors was tested with clinical grade anti-PD1 plus Fc-active or Fc-reduced bivalent anti-TIGIT mAbs, yielding 28% (7/25) and 40% (10/25) IFN-γ response. The role of Fc format in modulating rilvegostomig's functionality was confirmed by testing rilvegostomig on different Fc backbones. Engineering rilvegostomig on a Fc-active or afucosylated format diminished IFN-γ response, with activity observed in 40% (6/15) and 30% (7/23) of the tumors, respectively.

Conclusions: Within our ex vivo model we observed that rilvegostomig promotes greater immune cell activation compared to clinical grade anti-PD1 and combinations of anti-PD1 + anti-TIGIT monoclonal antibodies, especially in the context of Fc-active anti-TIGIT mAbs. This suggests that the monovalent bispecific format of rilvegostomig enables greater anti-tumor activity due to its synchronized and localized inhibition of PD-1 and TIGIT. Additionally, rilvegostomig's Fc-reduced design prevents the depletion of PD-1+/TIGIT+ effector cells required for an optimal anti-tumor response. Ongoing analyses are dissecting the mechanisms driving the enhanced activity of rilvegostomig.

OA03.04 TNFSF8-Targeting CpG Peptide Vaccine Reduces ICB Pneumonitis While Boosting Cancer Immunotherapy Efficacy

Z-X. Rong, Z-P. Xu, X-T. Cai, Y-P. Zhang, Z-Y. Dong
Nanfang Hospital, Southern Medical University, Guangzhou/CN

Introduction: Non-small cell lung cancer (NSCLC) patients undergoing immune checkpoint blockade (ICB) face elevated risks of immune-related pneumonitis (irPneumonitis). Emerging evidence challenges prior assumptions by demonstrating that pneumonitis development adversely impacts survival outcomes, while corticosteroid interventions compromise antitumor efficacy. These dual clinical dilemmas underscore the urgent need for precision strategies that mitigate irPneumonitis and enhancing ICB therapeutic benefits.

Methods: Multi-modal analyses integrated real-world pharmacovigilance data (FAERS database), pan-cancer transcriptomics, and single-cell RNA sequencing (scRNA-seq) of peripheral blood mononuclear cells (PBMCs) and bronchoalveolar lavage fluid (BALF) from irPneumonitis cohorts. An ICB pneumonitis model was established via lung irradiation plus ICB treatment. An adoptive transfer model was used to confirm the pathogenic cell subsets. We engineered a peptide vaccine targeting TNFSF8 extracellular domains, adjuvanted with CpG ODN 1585 - a Th1-polarizing DNA oligonucleotide selected for its safety profile and antitumor synergy. Vaccine efficacy was quantified via ELISA and flow cytometry. Lung injury was assessed through wet/dry weight ratios (edema), hydroxyproline quantification (fibrosis), serum KL-6/SP-D biomarkers, and histopathology (H&E). A KrasLSL-G12D/+ Trp53flox/flox lung adenocarcinoma syngeneic tumor model induced by rAAV-Cre and immortalization was employed to evaluate the efficacy of combination therapy.

Results: Comparative single-cell analysis revealed TNFSF8+CD4+ T cells as hallmark effectors in irPneumonitis patients, showing significant enrichment in irPneumonitis PBMCs and BALF compared to controls. Adoptive transfer of these cells intensified ICB-induced lung pathology, with characteristic increases in alveolar wall thickening, immune cell infiltration, and parenchymal damage. A rationally designed TNFSF8 peptide vaccine adjuvanted with CpG ODN 1585 was produced. The engineered TNFSF8 peptide vaccine demonstrated effective induction of TNFSF8-specific antibodies confirmed by ELISA. Selective reduction of circulating TNFSF8+CD4+ T cells was evaluated via flow cytometry. Moreover, histopathological analysis demonstrated preserved alveolar architecture with diminished inflammatory infiltrates in vaccinated mice receiving ICB. Vaccination mitigated ICB-induced pulmonary edema (decreased wet/dry lung weight) and fibrotic progression (decreased hydroxyproline content). Serum pulmonary biomarkers (KL-6/SP-D) also reflected reduced lung injury in vaccinated mice receiving ICB. Crucially, vaccination synergized with anti-PD1 therapy to suppress tumor growth in Kras/Trp53-driven models without exacerbating pulmonary toxicity.

Conclusions: TNFSF8+CD4+ T cells constitute a pathogenic axis in ICB-associated pneumonitis. Our TNFSF8-targeted vaccine platform coupled with Th1-skewing CpG adjuvant demonstrates dual therapeutic advantages: mitigating irPneumonitis severity while enhancing antitumor immunity. This precision immunomodulatory approach addresses the critical need for toxicity-sparing and efficacy-enhancing strategies in ICB-treated NSCLC populations.

SUNDAY, SEPTEMBER 7, 2025 - 15:15 - 16:30

OA04.01 Perceptions of Dyspnea and Quality of Life Before and After Lung-Sparing Surgery: A Pilot Mixed Methods Study

M. Culligan[1], K. Mooney-Doyle[2], A. Tod[3], N.J. Klinedinst[2], S. Zhu[2], J.S. Friedberg[1], M. Regan[2]
[1]Temple University Hospital, Philadelphia/PA/USA ,[2]University of Maryland, Baltimore, Baltimore/MD/USA ,[3]University of Sheffield, Sheffield/GB

Introduction: Pleural mesothelioma (PM) is a rare, incurable cancer associated with asbestos exposure. Lung-sparing surgery aims to improve survival. Despite being deemed fit for surgery, some patients do not return to their baseline physical function and continue to experience many of their initial debilitating symptoms. By gaining a better understanding of the impact lung-sparing surgery has on a patient's breathing capacity, physical function, symptom burden and quality of life (QOL), surgical teams will be better able to prepare patients for surgery, support them through their recovery and improve their QOL and palliate their symptom burden.

Methods: This prospective convergent parallel mixed methods study aimed to compare qualitatively derived themes that influenced the experience of living with PM and the perception of dyspnea with QOL and dyspnea measures, before and three months after lung-sparing surgery. Qualitative and quantitative data were collected concurrently and analyzed independently before being merged to provide a comprehensive understanding of the lived experiences of dyspnea and QOL. Interpretive phenomenological analysis of the qualitative data was conducted. Descriptive statistics were used to characterize the participants and summarize the Dyspnea-12 and McGill Quality of Life-Extended (MQoL-E) questionnaire outcomes. Correlations and mixed model linear regressions were used to analyze pre-operative and post-operative measures. The group experiential themes were compared to the MQoL-E score, the eight individual QOL domains and the Dyspnea-12 scores. Analysis and interpretations were made to determine if the results were convergent or divergent.

Results: The mixed methods analysis revealed a general convergence between the quantitative quality of life and dyspnea data and the qualitative themes derived from participant interviews (Table 1). Participants who expressed significant physical or psychological distress in their interviews often had lower scores in corresponding quantitative measures. Divergence was observed, particularly in the psychological domain, after surgery. Quantitative data showed an overall improvement in psychological scores post-operatively, but interviews revealed that some participants continued to struggle with the mental aspects of dyspnea, even as their psychological domain scores improved.

Conclusions: These results provide valuable insight into patient experience before and after surgery and identify a complex interplay between QOL and dyspnea. While surgery may improve psychological and existential well-being, it exacerbates respiratory symptoms, highlighting the need for multidimensional perioperative care. The mixed methods approach allowed for a deeper understanding of the existential impact of living with mesothelioma and undergoing surgery, revealing the complex interplay between physical symptoms, emotional well-being and existential concerns.

Group Experiential Themes	Personal Experiential Themes	Quantitative Data	Convergence / Divergence
		Before Surgery	
Psychological *Mind supports body in the world*	>Emotional impact of a new reality, >Interplay of the mind-body experience, >Physical and psychological symptom experience, >Redefining normalcy and identity, >Mental strength to accept the diagnosis of mesothelioma.	Pre-operative psychological domain scores range: 9–40 (mean 28.25, SD 14.4)	**Convergence:** Some deeply impacted, others unaffected.
		After Surgery	
	>Redefining normalcy and identity, >Interplay of the mind-body experience.	Post-operative scores remained the same or increased, range 33–40 (mean 37.67, SD 2.58)	**Convergence:** Mental relief and mind-body connection
	>Dyspnea experience and psychological distress.	Moderate negative correlation between post-operative psychological domain and Dyspnea-12 scores (r = -0.490, N = 6, p = 0.324)	**Divergence:** Strong connection in interviews despite the moderate correlation
		Before Surgery	
Physical *Body fighting, enduring, adjusting and adapting in the world*	>Preserving life and guarding against disruption, >Symptom awareness disconnects, >Managing the symptom experience, >Fighting the impact on daily routine. >Multidimensional dyspnea experience.	Pre-operative physical domain scores range: 6–30 (mean 22.75, SD = 9.13)	**Convergence:** Varying levels of symptoms and life
		After Surgery	
	>Physical endurance and commitment to the future, >Resilience through adaptation, >Appreciation of regaining life while facing mortality, >Physical impact of recovery.	Post-operative scores remained the same or increased for 4/6 participants, range 16–30 (mean = 25.67, SD 5.279)	**Divergence:** Some continued limitations, others resumed pre-operative normality.
		Before Surgery	
Social *Others sharing and supporting body in the world*	>Balancing needing help and giving help, >Not being alone in the experience, >Navigating complex family experiences, >Importance of family support and protection.	Pre-operative social domain scores range: 19–30 (mean = 26.88 SD 3.94)	**Convergence:** Varying levels of perceived social support.
		After Surgery	
	>Gaining strength from support of others, >Importance of family support, >Not going it alone.	Post-operative scores remained the same or increased for 4/6 participants, range 26–30 (mean = 28.5 SD 1.76)	**Convergence:** Recognition of the importance of social support.
		Before Surgery	
Experiential *Facing an uncertain future of body living in the world*	>Balancing hope and reality; >Spiritual strength, >Peace and resilience; >Self-determination in the face of a life-threatening illness; >Focus on the future and life priorities; >Moving forward with knowledge and confidence.	Pre-operative existential domain scores range: 21–40 (mean 32.5 SD 6.18)	**Convergence:** Varying levels of existential impact.
		After Surgery	
	>Balancing hope and reality, spiritual strength, >Peace and resilience.	Post-operative scores remained the same or increased for all participants: range 27–40 (mean 35.67 SD 4.84)	**Convergence:** Sense of relief and renewed hope.

OA04.02 Implementation of Large Language Model and GraphRAG-Assisted Decision Support for Multidisciplinary Team Cancer Care

S. Chen, Y. Yang
The Third People's Hospital Of Chengdu, Chengdu/CN

Introduction: Lung cancer remains a leading cause of morbidity and mortality worldwide, with late diagnosis and misdiagnosis significantly impacting survival rates. Current multidisciplinary team (MDT) workflows are hindered by data fragmentation, inconsistent interpretation of guidelines, and limited integration of trial results. While traditional AI-powered Clinical Decision Support Systems (CDSS) have improved diagnostic accuracy and personalized treatment options, they still face limitations in data retrieval, contextual reasoning, and decision traceability. To address these challenges, we evaluated a novel approach combining large language models (LLMs) with GraphRAG technology.

Methods: We selected DeepSeek-R1, a reinforcement learning enhanced large language model, as foundation model for contextual reasoning and treatment option matching. We then developed a comprehensive knowledge graph integrating patient data from multiple sources, where nodes represented clinical entities (e.g., gene mutations, treatment types) and edges defined relationships between them. Publicly available clinical guidelines and evidences (e.g., NCCN, CSCO, industry consensus, abstracts from WCLC) were incorporated as reference nodes linked to patient-specific nodes to provide management recommendations.We retrospectively analyzed 283 MDT cases from January 2021 to February 2025 for model training and prospectively validated the performance of this approach in 8 real-world MDT cases through an Investigator-Initiated Trial (IIT). The LLM and GraphRAG-assisted recommendations were compared against MDT expert consensus decisions in our hospital. The primary outcome was agreement rate with MDT expert consensus. Exploratory outcomes included time to diagnosis and accuracy of decision traceability.

Results: The LLM and GraphRAG-assisted approach achieved an alignment rate of 88.9% (16/18) with MDT expert consensus. Misalignment occurred due to failure in clinical entity extraction for a patient undergoing multiple treatment lines and uncollected innovative clinical findings (e.g., LAURA trial data) during graph construction. For exploratory endpoints, the average response generation time was 3.2 minutes, significantly faster than the traditional expert-consensus mode (5.6 minutes). The model demonstrated 100% traceability for recommended treatment options, including their sources and source links.

Conclusions: The LLM and GraphRAG-assisted approach represents an innovative AI tool that enhances the accuracy and efficiency of lung cancer MDT discussions. Future development should focus on prospective validation across diverse patient populations and integration with existing clinical systems to maximize adoption and improve patient outcomes.

OA04.03 Association of Pre- and Postdiagnosis Physical Activity, Promotion, and Maintenance With Lung Cancer Survival: A Nationwide Cohort Study

Y.W. Kim, K.I. Kwak, A-R. Choi, E.J. Park, B.J. Lee, Y.J. Lee, C-T. Lee
Seoul National University Bundang Hospital, Seongnam/KR

Introduction: Physical activity (PA) is important for improving life expectancy and is suggested as a prognostic factor for certain cancer types. However, the association between PA and mortality outcomes in survivors of lung cancer remains unclear.

Methods: We conducted a nationwide cohort study involving 23,257 individuals diagnosed with lung cancer between January 1, 2010, and December 31, 2016, who attended the National Health Screening Program within 2 years before and after diagnosis. Pre- and postdiagnosis PA levels and changes in PA levels before and after diagnosis were measured. All participants were followed up from the date of diagnosis to December 31, 2022 for the outcome of mortality.

Results: During the follow-up period of 165,344.0 person-years, 9,094 deaths occurred (6,633 lung cancer-specific and 2,461 non-lung cancer deaths). Multivariable analyses revealed that prediagnosis PA was associated with significantly reduced risk of all-cause (adjusted hazard ratio [aHR]=0.89, 95% confidence interval [CI]=0.85-0.94) and lung cancer-specific (aHR=0.90, 95% CI=0.85-0.95) mortality compared with inactivity. Similarly, post-diagnosis PA was associated with a significantly reduced risk of mortality outcomes (aHR=0.82, 95% CI=0.78-0.86 for all-cause and aHR=0.85, 95% CI=0.81-0.90 for lung cancer-specific mortality). When stratified by the total amount of PA (in MET-min/week), a significant dose-response relationship was observed between both pre- and postdiagnosis PA levels and mortality risk reduction. Compared with individuals who were consistently inactive before and after diagnosis, significant mortality risk reduction was seen in those who maintained PA (aHR=0.72, 95% CI=0.67-0.78 for all-cause and aHR=0.76, 95% CI=0.69-0.82 for lung cancer-specific mortality) and those who promoted PA after lung cancer diagnosis (aHR=0.89, 95% CI=0.84-0.94 for all-cause and aHR=0.92, 95% CI=0.86-0.98 for lung cancer-specific mortality). However, individuals who were active before diagnosis but became inactive after diagnosis showed no significant difference in survival outcomes compared with those who were consistently inactive.

Conclusions: Both pre- and postdiagnosis PA are associated with reduced mortality in survivors of lung cancer in a dose-response manner. Maintenance and promotion of PA after diagnosis are key to achieving optimal benefits in overall survival.

Introduction: Older adults with advanced thoracic cancers experience several unmet supportive care needs. Poor physical function and negative mood are risk factors for functional decline among patients receiving cancer treatment. This study reports planned interim analyses from a Phase II randomized control trial (RCT) examining novel virtual health physical therapy (PT) plus progressive muscle relaxation (R) supportive care interventions delivered to older adults with advanced thoracic cancer.

Methods: This prospective RCT (NCT05339022) accrued older adults ≥ 60 years of age with an advanced thoracic cancer (NSCLC, mesothelioma, or SCLC). Participants in the intervention group were evaluated by PT, given an exercise peddler, resistance bands, and completed 12 weekly PT and R sessions. Patients were provided a R recording for between-session practice. PTs evaluated participants in-person at the start and end of the 12-session intervention with the remainder of sessions conducted via virtual health. Relative perceived effort using the Borg Rating Scale was used to evaluate level of physical activity intensity. Participants in the standard of care (SOC) group received a referral to physical therapy and were provided the R instructions + recording. Patient-reported outcomes were conducted at baseline, weeks 4, 7, 10, and end of study (EoS) with the Short Physical Performance Battery (SPPB) and PROMIS Fatigue conducted at baseline, week 7, and EoS.

Results: To date, 100 participants consented to the ROAR study (intervention, n=50; SOC, n=50), 90% of which began the study (intervention, n=42; SOC, n=48). Nine patients withdrew prior to study start with one participant pending intervention start. Thus far, 60 participants have completed the study (intervention, n=26; SOC, n=34), with 6 participants still actively participating (intervention, n=1; SOC, n=5). 26 participants (29%) dropped out prior to study completion for the following reasons: death n=5, hospice transition n=5, became ineligible n=2, withdrew n=8, and LTFU n=4. Planned interim analyses demonstrate fatigue significantly decreased among the intervention group pre-post intervention compared to the SOC group (Cohen's D: 0.85 (95% CI: 0.18, 1.5), p=.02, Figure 1). SPPB scores improved a full point pre-post in the intervention group but not in the SOC group.

Conclusions: The ROAR-LCT intervention is the first study in the U.S. to demonstrate feasibility and preliminary efficacy among older adults with advanced thoracic cancer. Significant improvements in fatigue can improve physical and functional resiliency in this high-risk, vulnerable patient population. This trial in progress will be presented in full at the meeting.

Introduction: IMpower130 study demonstrated efficacy of atezolizumab plus chemotherapy (chemo) over chemo alone. IMpower150 study demonstrated efficacy of atezolizumab plus chemo with bevacizumab over bevacizumab plus chemo in nonsquamous non-small cell lung cancer (nsNSCLC) as first-line treatment. PD-1 inhibitors plus chemo have also demonstrated efficacy over chemo. However, whether the combination of a PD-1 inhibitor plus bevacizumab and chemo can provide further survival benefits, especially when comparing to PD-1 inhibitor plus chemo is still unknown. This study, for the first time, evaluated serplulimab (anti-PD-1 antibody) plus HLX04 (bevacizumab biosimilar) and chemo (pemetrexed plus carboplatin) versus serplulimab plus chemo in nsNSCLC.

Methods: This was a three-arm, randomized, double-blind, multicenter, phase 3 study. Patients with locally advanced or metastatic nsNSCLC without EGFR sensitizing mutations or ALK/ROS1 rearrangements and no prior systemic therapy were randomized 1:1:1 to receive serplulimab + HLX04 + chemo (group A), serplulimab + chemo (group B), or chemo (group C). Serplulimab and HLX04 were given every 3 weeks. The primary endpoint was the IRRC-assessed progression-free survival (PFS) per the RECIST version 1.1. Secondary endpoints included other efficacy endpoints and safety.

Results: From November 25, 2019 to June 15, 2023 (data cutoff date), 636 patients were randomized to group A (n=212), B (n=214), or C (n=210). The median follow-up duration was 23.4 (95% CI, 21.6-24.9), 23.1 (95% CI, 21.4-25.6), and 23.0 (95% CI, 20.7-25.6) months for the respective groups. Median PFS was significantly prolonged in group B than in group C (11.0 months vs. 5.6 months; stratified HR = 0.55, 95% CI 0.43-0.69, P < 0.0001), meeting the superiority criterion specified in the protocol. A numerical benefit in PFS was observed for group A compared to group B (12.6 months vs. 11.0 months, HR = 0.86, 95% CI 0.67-1.11, P=0.2529). Overall survival was not mature. Other efficacy results are listed in Table 1. Treatment-related adverse events leading to death occurred in 10 (4.7%), 5 (2.3%), and 7 (3.3%) patients in the respective groups.

Table 1. IRRC-assessed efficacy in ASTRUM-002.

Parameter	Group A (n=212)	Group B (n=214)	Group C (n=210)
Median PFS, months (95% CI)	12.6 (8.7, 14.0)	11.0 (8.4, 12.7)	5.6 (4.8, 6.8)
Stratified HR (95% CI)*	0.86 (0.67, 1.11)	0.55 (0.43, 0.69)	
p-value*	0.2529	<0.0001	
Brain metastases			
Yes	9.7 (7.4, 22.1)	8.1 (6.4, 11.0)	4.1 (3.0, 5.7)
Stratified HR (95% CI)*	0.65 (0.36, 1.14)	0.51 (0.30, 0.87)	
No	13.3 (8.5, 15.0)	11.2 (9.0, 15.1)	6.2 (5.0, 7.1)
Stratified HR (95% CI)*	0.93 (0.70, 1.22)	0.56 (0.43, 0.73)	
Confirmed objective response rate, n (%)	116 (54.7)	113 (52.8)	58 (27.6)
95% CI	47.8, 61.6	45.9, 59.7	21.7, 34.2
Confirmed median duration of response, months (95% CI)	18.3 (11.2, 29.1)	15.4 (11.0, 21.2)	9.7 (5.5, 13.9)

* Statistical comparison: group A versus B, group B versus C.

Conclusions: The addition of serplulimab to chemo provided significantly longer PFS compared to chemo alone in patients with locally advanced or metastatic nsNSCLC, while the combination of serpluliamb, bevacizumab and chemo provided numerical improvements in PFS when compared to serplulimab and chemo. Both treatment regimens had manageable safety profiles.

Introduction: For advanced non-small cell lung cancer (NSCLC), the combination of chemotherapy (CT) with an immune checkpoint inhibitor (ICI) in first-line treatment is now the standard of care. The benefit of adding immunotherapy (IO) to CT was not investigated by dedicated studies for elderly people. The IFCT-1805 ELDERLY trial assessed the addition of atezolizumab (ATZ), an ICI targeting the human programmed death-ligand 1 (PD-L1), to the current standard of care by monthly carboplatin with weekly paclitaxel CT (E Quoix et al, Lancet 2011) in elderly patients with advanced NSCLC.

Methods: We conducted a multicenter phase III randomized (2:1) trial in patients aged 70-89 years, with metastatic or locally advanced non-irradiable NSCLC (with neither EGFR mutation nor ALK rearrangement) naïve of treatment, to compare monthly carboplatin and weekly paclitaxel with (CT+IO arm) and without ATZ (CT arm). The patients were required to have a performance status (PS) 0-1 and mini-mental score ≥ 24. The primary endpoint was overall survival (OS). Secondary endpoints included progression-free survival (PFS), best response rate (ORR), duration of response (DOR) and safety.

Results: In total, 510 patients were randomized: 340 in the CT+IO arm and 170 in the CT arm, with a median age of 77 (range 70 - 89), male/female in 73%/27% cases, PS 0/1 in 27%/73% and 87% of current and ex-smokers. The main histologies were adenocarcinoma in 69% and squamous in 23%, with 49% and 51% of PD-L1 - and + (≥1%) tumours, respectively. Stage IV represented 94% of the patients. The median follow-up time was 38 months (ms). The median OS was 18.6 ms (95% CI 15.5-22.4) for CT+IO arm vs 15.0 ms (95% CI 11.8-17.5) for the CT arm with no statistically significant difference (HR 0.87 [0.70-1.08], p=0.20). The PFS was significantly improved by IO with a median PFS of 7.4 ms (95% CI 6.0-7.8) vs 5.7 ms (95% CI 5.4-5.8), respectively (HR 0.56 [0.46-0.69], p<0.0001). The ORR were 51.2% and 41.8% (p=0.04) and the median DOR were 6.7 ms vs 3.8 (p<0.0001), respectively. Second-line treatment was IO in 9.6 % and 55.5%, respectively. PD-L1 expression had borderline prognostic value (HR 0.81 [0.66-1.00], p=0.05), but no predictive value (p interaction=0.14). The safety analyses showed grade ≥3 treatment-related adverse events (TRAE) in 71.4% vs 61.9% (p=0.03) and grade ≥3 serious TRAE 16.3% vs 7.7% (p=0.008), in the CT+IO and CT arms respectively, with 5 grade 5 TRAE in the CT+IO arm (2 CT- and 3 IO-related) and 0 in the CT arm.

Conclusions: In the IFCT-1805 ELDERLY trial, despite a numerically longer OS when adding ATZ to the current standard of care CT for first line therapy of elderly patients with NSCLC, the gain was not statistically significant. However, the addition of ATZ to CT significantly improved the PFS, the ORR and the DOR regardless of PD-L1 expression.

Introduction: Chemotherapy plus immunotherapy is effective and safe in patients with advanced non-small cell lung cancer (NSCLC) with untreated brain metastases (BM). Dual immunotherapy plus a short chemotherapy course achieved high intracranial efficacy in patients with previously treated BM. This combination was investigated in patients with untreated BM in the NIVIPI-BRAIN trial (NCT05012254).

Methods: This open-label phase 2 study evaluated the efficacy and safety of two cycles of platinum-based chemotherapy (according to the histological type) combined with nivolumab 360mg Q3W plus ipilimumab 1mg/kg Q6W. Treatment was maintained until tumor progression, unacceptable toxicity, or up to 2 years. Patients with multiple, untreated and measurable BM, ECOG PS 0-1, EGFR/ALK/ROS1 negative, were assigned to 2 cohorts: (A) Asymptomatic BM without systemic corticosteroids; (B) Olygosymptomatic BM causing neurologic signs and symptoms controlled with ≤ 4mg qd of dexamethasone. Primary endpoint: to determine the 6 and 5 months (m) intracranial PFS rate by RANO-BM criteria for cohort A and B, respectively.

Results: 66 patients were included and 65 patients were finally treated (39 in cohort A and 26 in cohort B). Median age was 64 years and most patients were males (73%), ever smokers (89%) and had lung adenocarcinoma (77%). The median number of cycles of nivolumab and ipilimumab were 5 and 3, respectively, and 8 patients (12%) completed 2 years of treatment. Treatment discontinuation was mainly due to progression (55%) and toxicity (20%). Systemic and intracranial ORR was 41.5% (27 PR for systemic and 6 CR / 21 PR for intracranial). The 6m intracranial PFS rate was 41% (95% CI 28.2-59.8) for cohort A and 5m intracranial PFS rate was 46.2% (95% CI 30.5-69.9) for cohort B, both below the expected 50%. The median intracranial PFS was shorter than systemic PFS (4.9 vs 6.7 months). With a median follow-up of 25 months, the median OS was 10.6 months and the 2-year OS rate was 29.4% in the whole cohort. Most neurological adverse events (AEs) were G1-2, and 7 patients had G3 (1 seizure, 1 cognitive impairment, 1 headache, 1 limbs weakness, 1 polyneuropathy, 1 disorientation, 1 stroke) and 1 patient had a G4 seizure. Treatment-related AEs (TRAEs) with immunotherapy were observed in 78.5% of patients. No G5 TRAEs were reported.

Conclusions: The combination of nivolumab plus ipilimumab and two cycles of chemotherapy did not reach the expected intracranial efficacy in patients with advanced NSCLC with untreated BM.

Table 1. Efficacy outcomes in the NIVIPI-BRAIN clinical trial.

	Cohort A (n=39)	Cohort B (n=26)	Total (n=65)
Systemic ORR/DCR (%)	43.6 / 84.6	38.5 / 69.3	41.5 / 78.4
Intracranial ORR/DCR (%)	41 / 69.2	42.3 / 80.8	41.5 / 73.8
Median syst. PFS, months (95% CI)	6.8 (4.6-11.4)	5.8 (3.3-NR)	6.7 (4.3-11)
Median ic. PFS, months (95% CI)	5 (3.6-8.4)	4 (3.5-14)	4.9 (3.7-8.3)
6 months syst. PFS rate (%)	53.8	46.2	50.8
6 months ic. PFS rate (%)	41.0	42.3	41.5
Median OS, months (95% CI)	10.6 (5.8-21.9)	10.2 (6.7-NR)	10.6 (7.5-21.9)
1 year OS rate (%)	39.9	46.2	42.6

Introduction: Niraparib, a poly(ADP-ribose) polymerase inhibitor, has demonstrated efficacy in ovarian cancer. The ZEAL-1L study was designed to assess the combination of niraparib plus pembrolizumab in patients with advanced or metastatic non-small cell lung cancer (NSCLC) in the maintenance-therapy setting.

Methods: In ZEAL-1L, a multicenter, randomized, double-blind, placebo-controlled phase 3 study, niraparib plus pembrolizumab was compared with placebo plus pembrolizumab as maintenance therapy in patients with advanced/metastatic stage IIIB/IIIC and stage IV NSCLC presenting with stable disease, partial response (PR), or complete response (CR) per investigator's assessment after 4-6 cycles of first-line standard-of-care platinum-doublet chemotherapy plus pembrolizumab. Patients were randomized 1:1 to receive niraparib (300 mg for baseline body weight ≥77 kg and baseline platelet count ≥150,000/µL; 200 mg for baseline body weight <77 kg and/or baseline platelet count <150,000/µL) or matched placebo once daily plus maintenance pembrolizumab every 3 weeks until radiographic progression, unacceptable toxicity, or death. Primary and key secondary endpoints are shown in Table 1.

Table 1. Efficacy endpoints

Endpoint	Niraparib plus pembrolizumab (n=331)[a]	Placebo plus pembrolizumab (n=335)[a]
Primary endpoint		
PFS by BICR in patients with a best response of PR or CR, median (95% CI), mo	n=200	n=201
	5.6 (4.14–8.28)	5.6 (4.21–7.16)
	HR, 1.00 (95% CI, 0.79–1.27) 1-sided P=0.502	
Key secondary endpoints		
PFS by BICR in the ITT population, median (95% CI), mo	4.4 (95% CI, 4.17–5.52)	4.4 (95% CI, 4.14–5.52)
	HR, 0.99 (95% CI, 0.82–1.19)	
OS in patients with a PR or CR, median (95% CI), mo	n=200	n=201
	24.8 (20.11–31.44)	32.5 (24.67–NE)
	HR, 1.20 (95% CI, 0.92–1.56)	
OS in the ITT population, median (95% CI), mo	21.4 (18.23–23.23)	25.3 (21.22–28.71)
	HR, 1.16 (95% CI, 0.96–1.41)	
TTP-CNS by BICR using RANO-BM criteria in the ITT population, cumulative incidence competing risk analysis	Subdistribution HR, 0.98 (95% CI, 0.63–1.52)	

[a]Reflects ITT population for each arm.
BICR, blinded independent central review; HR, hazard ratio; ITT, intention-to-treat; NE, not estimable; OS, overall survival; PFS, progression-free survival; RANO-BM, response assessment in neuro-oncology brain metastases; TTP-CNS, time to progression in the central nervous system.

Results: Overall, 331 patients were randomized to niraparib plus pembrolizumab, and 335 to placebo plus pembrolizumab; 194 (29%) had squamous histology, and 472 (71%) had nonsquamous histology by randomization stratification factor. At data cutoff (26Feb2025), median follow-up time for OS was 34.30 months for patients in the niraparib-plus-pembrolizumab arm and 33.45 months for patients in the placebo-plus-pembrolizumab arm, and 443 patients (67%) had discontinued from the study (n=373 [56%] died). Primary and key secondary efficacy endpoint data are shown in Table 1. Safety was consistent with the known safety profiles of niraparib and pembrolizumab (Table 2). There were 4 treatment-related TEAE deaths (niraparib-plus-pembrolizumab arm: sudden death [n=1], pneumonitis and pulmonary embolism [n=1]; placebo-plus-pembrolizumab arm: colitis [n=1], pneumonia [n=1]).

Conclusion: Niraparib failed to improve BICR-assessed PFS in the CR/PR population; no efficacy benefit was detected in key secondary endpoints.

Introduction: QLC5508 (MHB088C), a novel B7-H3-targeted antibody-drug conjugate with high cell-binding activity and internalization rate, contains SuperTopoiTM payload which is 5 to 10 times more potent than Dxd. The preliminary data of a phase 1 study indicated the promising anti-tumor activity and tolerability of QLC5508 in patients with solid tumors, including extensive-stage small cell lung cancer (ES-SCLC). Here we report the updated results of survival and safety in patients with ES-SCLC.

Methods: This multi-center phase 1 trial consisted of dose-escalation stage and dose-expansion stage. In dose-escalation stage, QLC5508 was administered via intravenous infusion at dosage ranging from 0.8 mg/kg to 4.0 mg/kg every two (Q2W) or three weeks (Q3W). In dose-expansion stage, patients with ES-SCLC who failed platinum-based systematic chemotherapy±PD-1/PD-L1 and had no more than three lines of prior treatment or intolerable to standard treatment were recruited. Dose levels of 1.6 mg/kg Q2W, 2.0 mg/kg Q2W, and 2.4 mg/kg Q3W were selected for dose-expansion stage. The primary endpoints were safety and tolerability.

As of Jun 13, 2025, a total of 106 patients were included in 1.6 mg/kg Q2W (n=30), 2.0 mg/kg Q2W (n=46), and 2.4 mg/kg Q3W (n=30) dose levels. Most of the patients (90.6%) had stage IV disease. There were 28 patients (26.4%), 15 patients (14.2%), and seven patients (6.6%) who had previously received 2, 3, >3 lines of treatment, respectively. Over half of the patients (58.5%) had received immunotherapy. Eleven (10.4%) patients had prior treatment of irinotecan. Treatment-related adverse events (TRAEs) of ≥grade 3 occurred in 15 (50.0%), 16 (34.8%), and 13 (43.3%) patients in 1.6 mg/kg Q2W, 2.0 mg/kg Q2W, and 2.4 mg/kg Q3W cohorts, respectively. The most common TRAEs of ≥grade 3 with incidence of ≥10% were neutrophil count decreased (17.0%) and white blood cell count decreased (10.4%). Two (4.3%) patients discontinued the treatment due to TRAEs of interstitial lung disease, both were in the 2.0 mg/kg Q2W cohort. One patient (3.3%) died due to treatment-related cachexia in the 1.6 mg/kg cohort. In the efficacy set (n=103), median progression-free survival was 5.55 (95% confidence interval [CI], 3.65-6.31), 5.95 (95% CI, 4.63-8.15), and 5.52 (95% CI, 3.81-7.06) months in 1.6 mg/kg Q2W, 2.0 mg/kg Q2W, and 2.4 mg/kg Q3W cohorts, respectively. The overall survival in the three cohorts were 11.50 (95% CI, 7.00-13.34), 11.73 (95% CI, 8.77-not evaluable [NE]), and 11.50 (95% CI, 7.59-NE) months, respectively. In conclusion, QLC5508 showed prolonged survival as well as manageable and tolerable safety profile in previously treated patients with ES-SCLC. QLC5508 2.0 mg/kg Q2W is being evaluated in an ongoing phase 3 study.

Introduction: Seizure-related homolog protein 6 (SEZ6) is highly expressed in small cell lung cancer (SCLC). ABBV-706, an antibody-drug conjugate (ADC) comprising a SEZ6-targeting antibody with a topoisomerase 1 inhibitor (Top1i) payload, was evaluated in a phase 1 study (NCT05599984). Preliminary results from dose escalation (1.3 to 3.5 mg/kg Q3W) showed encouraging antitumor activity and manageable safety of ABBV-706 monotherapy in patients with advanced solid tumors (JCO 2024;42:suppl16;abstr 3001). We present updated safety and efficacy results for patients with SCLC in the dose optimization cohorts.

Methods: Patients (≥18 years) with relapsed/refractory (R/R) SCLC were randomized to receive ABBV-706 at 1.8 or 2.5 mg/kg Q3W until disease progression/unacceptable toxicity. SEZ6 expression was assessed retrospectively. Patients with prior treated or untreated stable brain metastases were eligible. Prior exposure to SEZ6-targeted ADCs or ADCs with Top1i payload was not permitted. Primary objectives were to assess efficacy, safety, pharmacokinetics, and determine the recommended phase 2 dose (RP2D) in SCLC.

Results: In total, 80 patients with SCLC were enrolled: 1.8 mg/kg, n=41; 2.5 mg/kg, n=39. Median number of prior therapies was 2 (range: 1-6); median treatment duration was 5.8 months (range: 0.7-11.3). SEZ6 expression and patient characteristics were balanced between the dose cohorts. ABBV-706 showed similar ORR at both doses, with longer DOR and PFS at 1.8 mg/kg (see Table). ORR was higher in patients who were Top1i naive and/or receiving ABBV-706 in second line (62.1% and 81.3% at 1.8 mg/kg). The 1.8-mg/kg dose had improved safety vs 2.5 mg/kg. Relative dose intensity was 99% and 85% at 1.8 mg/kg and 2.5 mg/kg. Any-grade (G) treatment-related adverse events (TRAEs) in the 1.8-mg/kg and 2.5-mg/kg cohorts occurred in 85% and 95% of patients; most common were anemia (51% vs 74%) and fatigue (34% vs 39%). G≥3 TRAEs in the 1.8-mg/kg and 2.5-mg/kg cohorts occurred in 49% and 77% of patients; anemia (39% vs 62%) and neutrophil count decreased (17% vs 31%) were most common. Serious TRAEs occurred in 17% (1.8 mg/kg) and 10% (2.5 mg/kg) of patients. Overall, TRAEs leading to dose discontinuation, interruption, reduction, and death occurred in 9%, 44%, 28%, and 4% of patients. Adjudicated interstitial lung disease rate was 9%.

Conclusions: ABBV-706 has manageable safety and promising efficacy in patients with R/R SCLC. Based on the totality of the benefit-risk profile, monotherapy RP2D was determined to be 1.8 mg/kg Q3W in SCLC.

Table. Efficacy outcomes in patients with SCLC in the DO cohorts

Outcome	1.8 mg/kg (n=41)	2.5 mg/kg (n=39)	DO Overall (N=80)
Median follow-up, months	9.0	8.3	8.4
ORR[a], n/N (%)	23/41 (56.1)	23/39 (59.0)	46/80 (57.5)
1 prior LOT	13/16 (81.3)	10/14 (71.4)	23/30 (76.7)
≥2 prior LOT	10/25 (40.0)	13/25 (52.0)	23/50 (46.0)
Top1i naive	18/29 (62.1)	18/28 (64.3)	36/57 (63.2)
Top1i exposed	5/12 (41.7)	5/11 (45.5)	10/23 (43.5)
Brain metastasis	10/16 (62.5)	6/12 (50.0)	16/28 (57.1)
Median DOR, months [95% CI]	6.2[b] [4.2, NE]	4.4[b] [3.5, 6.9]	5.6[c] [4.2, 6.9]
Median PFS, months [95% CI]	6.8 [4.0, 8.2]	5.6 [4.4, 7.0]	5.7 [4.9, 7.0]
9-month OS, probability [95% CI]	0.6 [0.4, 0.7]	0.6 [0.4, 0.7]	0.6 [0.5, 0.7]

OA07.01 Final Analysis of Brighstar: LCT With Brigatinib in Tyrosine Kinase Inhibitor-Naïve ALK-Rearranged Metastatic NSCLC

Y. Elamin[1], S. Gandhi[2], X. Han[2], S. Heeke[2], D. Sui[2], M.B. Antonoff[2], D.L. Gibbons[2], X. Le[2], M. Negrao[2], V.K. Lam[3], M. Altan[2], H. Tran[2], J. Tu[2], C.M. Gay[2], L. Byers[2], T. Cascone[2], G. Blumenschein Jr[2], J. Chang[2], A. Vaporciyan[2], Z. Liao[2], S. Swisher[2], J. Zhang[2], J. Lee[2], J. Wu[2], J. Heymach[2]
[1]University of Texas MD Anderson Cancer Center, Houston/TX/USA ,[2]MD Anderson Cancer Center, Houston/TX/USA ,[3]John Hopkins, Maryland/MD/USA

Introduction: Approximately 95% of patients who have an initial response to ALK-TKIs exhibit an incomplete response, resulting in residual disease that may enable emergence of acquired resistance. Minimizing or eliminating residual disease with local consolidative therapy (LCT) may delay development of resistance and improve clinical outcomes.

Methods: BRIGHTSTAR is a single-center investigator-initiated trial assessing the safety and efficacy of brigatinib with LCT. Eligible patients with TKI-naïve ALK-rearranged advanced NSCLC with oligo- and poly-metastatic disease, were treated for 8 weeks with induction brigatinib followed by LCT with radiation and/or surgery. (ClinicalTrials.gov Identifier: NCT03707938). Baseline and post-brigatinib induction tumor images were comprehensively annotated. Disease burden was defined by overall 3D tumor volume. Individual patient data from a phase 3 trial of brigatinib vs crizotinib (ALTA-1L, NCT02737501) were retrospectively compared. Herein, we present the final analysis of the study.

Results: A total of 34 patients were enrolled, of whom 32 (94%) proceeded to LCT. At study entry, most patients (82%, n=28) had polymetastatic disease (>3 sites) and 41% (n=14) had brain metastases. LCT modalities included radiation (n=27), surgery (n=3), and surgery + radiation (n=2). LCT-related grade ≥3 adverse events included esophagitis (9%), pneumonitis (3%), anemia (3%), adrenal insufficiency (3%), and bronchopulmonary hemorrhage (3%). One patient with grade 3 pneumonitis successfully transitioned to full-dose alectinib after resolution with corticosteroids. The median PFS was 66 months (95%CI: 27.4 months to not reached (NR))., with a 5-year PFS rate of 51% (95%CI: 33 to 69). For comparison, in the ALTA-1L trial, in which patients received brigatinib alone, median PFS was 29.4 months. A post hoc analysis showed that patients who underwent comprehensive consolidation (n = 20) had a median PFS that was not reached, whereas those who received partial consolidation (n = 12) had a median PFS of 26 months (95%CI: 16.4 to 29.0 months, ($p<0.001$). Additionally, among patients with baseline ctDNA positivity (n = 16), median PFS was 28 months (95%CI: 18.2 months to NR), while it was not reached in patients with ctDNA negativity (n = 13). Patients with baseline total tumor volume greater than 55 cm^3 experienced a median PFS of 27.5 months (95% CI: 25.03 months to NR), whereas the median PFS was not reached in those with a baseline total tumor volume of 55 cm^3 or less. Using multivariant analysis incorporating these variables, patients were stratified into high- and low-risk groups, with high-risk group showing significantly worse PFS (HR 11.6, 95% CI:2.51-53.8).

Conclusions: Brigatinib with LCT is safe in patients with ALK-rearranged advanced NSCLC and yielded promising results when compared to historical outcomes from brigatinib alone. Patients who received comprehensive LCT had superior outcomes, and baseline ctDNA status and radiological volumetric measurements may serve as prognostic biomarkers for treatment response.

OA07.02 Tumor Burden Metrics at Oligoprogression and Survival After SBRT in NSCLC: An Analysis of the Randomized Phase II CURB Trial

M.T. McMillan[1], C.J. Tsai[2], T. Chaunzwa[1], J.T. Yang[3], A.J. Schoenfeld[1], P. Iyengar[1], N. Shaverdian[1], N. Riaz[1], D.R. Gomez[1]
[1]Memorial Sloan-Kettering Cancer Center, New York/NY/USA ,[2]Princess Margaret Cancer Centre, Toronto/ON/CA ,[3]New York University, New York/NY/USA

Introduction: The CURB trial (NCT03808662) demonstrated that adding stereotactic body radiotherapy (SBRT) to the standard of care significantly prolonged progression-free survival (PFS) in patients with oligoprogressive non-small cell lung cancer (NSCLC). While tumor burden may have played a role in outcomes, it remains unclear which tumor burden metrics are most impactful in stratifying patient risk. To this end, we performed a secondary analysis of the SBRT-treated NSCLC cohort to assess the correlation of various burden metrics with PFS and overall survival (OS).

Methods: We analyzed clinical and tumor characteristics at the time of oligoprogression in patients with NSCLC randomized to SBRT plus standard of care in the phase II CURB trial. Tumor burden parameters evaluated for association with PFS and OS included: (a) total number of growing lesions (TGL), (b) total number of lesions (TNL), (c) sum of longest diameters (SLD) of all lesions (SLD-AL), (d) SLD of growing lesions (SLD-GL), and (e) SLD of stable and regressing lesions (SLD-SRL). We also examined the impact of patterns of oligoprogression, defined as progression in new vs. known lesions, on outcomes. Survival was analyzed using Kaplan-Meier estimates and log-rank tests; multivariable associations were assessed using Cox regression.

Results: Among 31 NSCLC patients who received SBRT, a lower SLD-GL at the time of oligoprogression was associated with longer PFS: patients with a SLD-GL ≤ 4.0 cm (i.e., the median SLD-GL) had a PFS of 20.0 months vs 4.5 months in those with a SLD-GL > 4.0 cm (p=0.047). A SLD-GL ≤ 4.0 cm was also associated with superior OS compared to a SLD-GL > 4.0 cm (60.5 months vs 10.8 months, p<0.001). Conversely, the SLD-AL and SLD-SRL were not associated with PFS (p=0.943 and p=0.436, respectively) or OS (p=0.112 and p=0.297, respectively). The TNL at oligoprogression (i.e., ≤ 5 vs > 5) was not associated with PFS (p=0.732) or OS (p=0.264). Additionally, TGL at oligoprogression was not associated with PFS (p=0.402); however, having only one TGL at oligoprogression was associated with superior OS compared to having ≥ 2 TGL (median: 52.8 months vs 13.6 months, p=0.028). Having at least one liver metastasis was associated with worse median OS (7.9 months vs 38.2 months, p=0.027) and a trend towards worse median PFS (1.7 months vs 10.1 months, p=0.123). The pattern of oligoprogression was not associated with PFS or OS. Histology, PD-L1 TPS, and targetable alterations were not associated with differential benefit. On multivariable analysis, lower SLD-GL at oligoprogression was associated with a reduced hazard for death and a trend toward reduced hazard for progression.

Conclusions: While "tumor burden" can be assessed with several approaches, in patients receiving SBRT in oligoprogressive NSCLC, the sum of longest diameters of all growing lesions was found to be most correlated with both PFS and OS. Our analysis suggests that this tumor burden metric should be prioritized with respect to treatment options in this context, warranting further exploration.

Maria" Hospital, Terni/IT ,[4]Radiology Centre "S. Maria" Hospital, Terni/IT ,[5]Thoracic Surgery Centre "S. Maria" Hospital, Terni/IT ,[6]Pathology Centre "S. Maria" Hospital, Terni/IT ,[7]Nuclear Medicine Centre "S. Maria" Hospital, Terni/IT

Introduction: Therapeutic advances such as targeted therapies (TT) and immunotherapy (IO) have dramatically improved the prognosis of patients with stage IV non-small-cell lung cancer (NSCLC). However, most patients eventually develop resistance to systemic therapy, with some having limited disease progression (ie, oligoprogression - oligo-P). We aimed to assess whether stereotactic ablative radiotherapy (SAbR) targeting oligo-P sites could improve patient outcomes. Here we report outcomes of the START-NEW-ERA #oligo non-randomized phase II trial (Clinical Trial NCT06207292) on the efficacy and safety of SAbR in oncogene addicted and non-oncogene addicted oligo-P NSCLC.

Methods: Patients with oligo-P (body) NSCLC defined on PET-CT, after having received at least first-line systemic therapy, were enrolled in a single centre non randomised phase II trial of SAbR. The primary endpoints were new systemic therapy-free survival (NST-FS) and safety.

Results: Between May 2015 and February 2025, 80 oligo-P NSCLC patients were enrolled. 66% and 34% were non-oncogene addicted and oncogene addicted, respectively and had ongoing IO (with or without chemotherapy) and TT. The median number of treated oligo-metastases were 4. The main site of oligo-P was the primary tumor followed by hilar-mediastinal nodes, bone and adrenal gland. After a median follow-up of 30 months (95% CI, 20 to 41) range (1-86 months) the median NST-FS was 34 months (95% CI, 21 to 49). The 1, 3, and 5-year NST-FS rates were 73 ± 5%, 48 ± 8% and 39 ± 10%, respectively. 15% have completed the systemic therapy according to natural completion; 11% have permanently suspended systemic therapy due to toxicity (not SAbR related) or poor compliance; 26% discontinued therapy due to poly-progression; 48% are undergoing the same therapy ongoing at the time of enrollment. 40% patients received at least one further cycle of SAbR on newly oligo-P site while maintaining the same ongoing systemic therapy. 21% developed brain oligo-metastases treated by stereotactic radiosurgery. The median PFS was 9 months (95% CI, 5 to 16). The 1-, 3- and 5- year PFS rates were 43 ± 6%, 23 ± 6% and 23 ± 6%, respectively. The median OS was 57 months (95% CI, 35 to 68). The 1, 3, and 5-year OS rates were 82 ± 4%, 60 ± 7% and 40 ± 9%, respectively. Only 9 patients had experienced local recurrence in one of oligo-P sites submitted to SAbR.Only 1 patient had experience ≥G3 lung toxicity.

Conclusions: The START-NEW-ERA #oligo non-randomized phase II trial confirms the safety and effectiveness of SAbR in oncogene addicted and non-oncogene addicted oligo-P NSCLC patients. Local treatment with SAbR extended the ongoing therapy for a median time of 34 months avoiding the switch to new systemic therapy suggesting that SAbR should be the standard of care in oligo-progressive NSCLC patients.

Introduction: Olomorasib, a potent and selective second-generation KRAS G12C inhibitor, demonstrated promising antitumor activity and a manageable safety profile in first-line (1L) KRAS G12C-mutant advanced NSCLC in combination with pembrolizumab plus chemotherapy (chemoimmunotherapy). Here, we report results of an integrated analysis in 1L patient (pts) who received olomorasib plus chemoimmunotherapy in LOXO-RAS-20001 (Phase 1) and the safety lead-in for SUNRAY-01 (Phase 3).

Methods: Pts with advanced KRAS G12C-mutant NSCLC, PD-L1 0-100% (ECOG PS 0-1) were assigned to olomorasib (50 or 100 mg, orally BID) with pembrolizumab plus chemotherapy (per label). One prior cycle of SOC was allowed when timely initiation of treatment was medically indicated. Safety was assessed across all treated pts. ORR was assessed in the efficacy evaluable population, including pts with ≥1 post-baseline response assessment or who discontinued treatment before the first response assessment.

Results: As of 15 January 2025, 78 pts received olomorasib plus chemoimmunotherapy, including 24 pts (31%) who received 1 cycle of SOC prior to enrollment; 35% were PD-L1 <1%, 40% were PD-L1 1-49%, and 22% were PD-L1 ≥50% (4% [3 pts] unknown). With a median follow-up of 5.5 months (IQR: 3.5-6.1), any grade treatment-related adverse events (TRAEs) in ≥20% of pts were nausea (37%), anemia (35%), fatigue (32%), diarrhea (30%), AST increased (27%) and ALT increased (26%). The most common grade ≥3 TRAEs were anemia (14%), neutrophil count decreased (12%), and ALT/AST increased (12%/12%). Cytopenias and hepatic events were overall manageable with dose adjustments and/or corticosteroids. TRAEs led to olomorasib dose reduction in 15% of pts, and discontinuation of all study treatment in 6% of pts. The ORR was 59% in all pts (n=75) regardless of PD-L1 expression, and 64% in pts who received olomorasib 100 mg BID (n=44). Responses were durable, with a median DOR of 10.5 months and median PFS of 11.6 months (Table 1). Updated data will be presented.

Conclusions: In this merged dataset with more than triple the number of 1L pts relative to prior presentations, olomorasib plus chemoimmunotherapy continues to demonstrate a manageable safety profile and promising efficacy across all PD-L1 levels. Moreover, efficacy remains promising in this higher-risk population, largely of pts with PD-L1 0-49%. These updated findings further support the ongoing Phase 3 SUNRAY-01 trial, comparing olomorasib (100 mg BID) plus chemoimmunotherapy versus placebo plus chemoimmunotherapy as 1L treatment in pts with KRAS G12C-mutant NSCLC and any PD-L1 level.

Table. Response and Time-To-Event Endpoints in the Efficacy Evaluable Population

	Olomorasib (50 mg or 100 mg BID) + Pembrolizumab + Pemetrexed + Platinum			
Endpoint	All pts* (PD-L1 0-100%) N = 75	Pts with PD-L1 < 1% N = 24	Pts with PD-L1 1-49% N = 31	Pts with PD-L1 ≥ 50% N = 17
ORR†, % (n/N)	59 (44/75)	58 (14/24)	58 (18/31)	71 (12/17)

Introduction: The combination of sotorasib, bevacizumab, and platinum-based chemotherapy may exert synergistic anti-tumor effects enhancing clinical outcomes in patients with NSCLCs harboring KRAS G12C mutations. We conducted a phase 2 trial evaluating the efficacy and safety of this novel first-line regimen in treatment-naïve, newly diagnosed advanced or recurrent NSCLC with KRAS G12C mutations.

Methods: SHERLOCK was an investigator-initiated, multicentre open-label trial across 13 sites in Australia. Study treatment consisted of sotorasib 960mg once daily with 4 cycles of induction carboplatin (AUC5), pemetrexed (500mg/m2) and bevacizumab (15mg/kg) every 3 weeks, followed by maintenance sotorasib, pemetrexed and bevacizumab every 3 weeks until disease progression. CT imaging was performed at baseline and every 8 weeks until disease progression. Plasma samples for ctDNA were obtained at baseline, week 8, week 16 and at progression. The primary endpoint was to determine the objective response rate (ORR) according to RECIST 1.1. Key secondary outcomes included progression-free survival (PFS) and adverse events.

Results: Between August 2022 and June 2025, a total of 52 participants were enrolled. Baseline characteristics were: median age 67 years; 62% female; 40% ECOG 0; 96% were former or current smokers; and 38% had brain metastases. Baseline tumor characteristics showed PD-L1 expression ≥50% in 23% (12/52). In ctDNA evaluable participants, baseline TP53 co-mutation occurred in 51% (19/37), STK11 in 30% (11/37), and KEAP1 in 16% (6/37). With a median follow-up of 20 months, 47 participants were evaluable for the primary endpoint. Unconfirmed ORR was 72% (34/47). Confirmed ORR was 62% (29/47). The median duration of unconfirmed and confirmed response was 9.0 and 7.5 months respectively. In PD-L1 evaluable participants, confirmed ORR according to PD-L1 ≥50%, 1-49%, and <1% was 80% (8/10), 58% (7/12) and 57% (13/23), respectively. Confirmed ORR for participants harboring plasma co-mutations in TP53, STK11, or KEAP1 was 79% (15/19), 64% (7/11) and 50% (3/6), respectively. Intracranial CNS response was documented in non-target lesions in 30% (3/10, none with prior radiotherapy). There were 63% PFS events (33/52) and median PFS was 9.0 months (95% CI 7.9-15). Median PFS according to PD-L1 ≥50%, 1-49%, and <1% was 15.0, 7.9 and 9.0 months respectively. In ctDNA evaluable population (n=37), median PFS according to TP53, STK11 or KEAP1 co-mutation was 11.0, 9.6 and 5.8 months respectively. Plasma KRAS G12C clearance was observed in 84% (27/32) of participants with paired baseline and week 8 samples, and in 85% (23/27) of those with paired baseline and week 16 samples. Among participants with confirmed ORR, 79% (23/29) had detectable plasma KRAS G12C mutations at baseline, and 95% (20/21) achieved clearance by week 8. Adverse events were consistent with the known safety profiles of each individual study drug with no new safety signals identified.

Conclusion: Sotorasib, in combination with bevacizumab and chemotherapy, demonstrated promising anti-tumor activity as a first-line treatment for advanced NSCLC with KRAS G12C mutation. High ORR were observed across all PD-L1 expression levels and molecular subgroups, including those with TP53, STK11, or KEAP1 co-mutations. These findings warrant further evaluation in a randomized phase 3 trial.

Introduction: A study by the International Association for the Study of Lung Cancer (IASLC) on the reproducibility of pathologic response (PR) assessment in surgically resected lung specimens after neoadjuvant therapy showed good interrater agreement between thoracic pathologists, though challenges remain. The aim of this study was to develop machine learning algorithms for quantifying tumor bed (TB) area and residual viable tumor (VT), and to compare these results to previously published assessment by pathologists from the IASLC reproducibility study.

Methods: The study included 72 patients with non-small cell lung carcinoma (NSCLC) from 5 clinical trials [NADIM phase II (NCT03081689), NEOSTAR phase II (NCT03158129), MPDL3280A (NCT02716038), TOP 1501 (NCT02818920) and MEDI4736 (NCT02904954)]. Hematoxylin and eosin (H&E)-stained glass slides were reviewed by five (N=25 patients) or six (N=47 patients) pathologists. Manual pathologist annotations (N=15,564) of regions including TB and VT were collected from whole slide images . Convolutional neural network models were trained using these annotations to classify tissue regions. TB detection was trained using a multi-resolution architecture. A separate Convex Hull algorithm (CHA) was applied to the VT region predictions to predict VT area in a manner more closely aligned with pathologist visual assessments. For both models, digital PR was computed at the case level as the percent of TB area that was VT , weighted by slide-level TB area. For each method (pathologist reads and both models) the PR percentage was calculated as the average PR percentages across slides (unweighted). PR from pathologist reads were averaged (average pathologist read [APR]). Correlation of PR values between the approaches was done with Spearman's correlation coefficient. Rater agreement was assessed with Cohen's Kappa statistic. The major pathologic response (MPR) cutoff for digital PR and CHA was determined by the matching percentile based on the APR percentage at 10%.

Results: There was strong correlation of PR percentages between approaches: APR vs. Digital PR (0.97), APR vs. CHA (0.97), and Digital PR vs. CHA (0.99). The APR was ≤10% (MPR) in 38.9% of the study patients. Digital PR and CHA were in perfect agreement for MPR. The kappa statistic was 0.82 (95% CI: 0.69, 0.96) for APR versus Digital PR/CHA with 6 discordant cases. Agreement was stronger for squamous cell carcinoma (Kappa 0.92, 95% CI: 0.76, 1.0) than for non-squamous carcinoma (Kappa 0.77, 95% CI: 0.59, 0.96). Survival analysis is ongoing.

Conclusions: Our study demonstrated the high concordance of PR assessment between machine learning algorithms and expert pathologists. Despite some discordances, the overall high level of agreement suports the utility of these machine learning approaches in ensuring accurate and standardized evaluations of PR in lung cancer clinical trials.

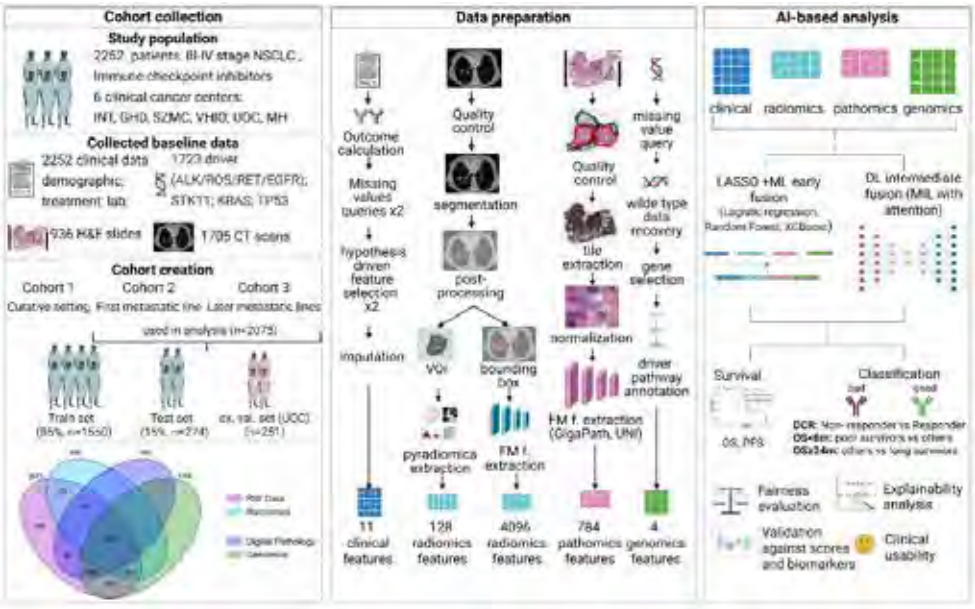
Introduction: Even after 10-years of immunotherapy (IO), treatment selection still depends on subgroup analyses/clinical scores, highlighting the urgent need for robust, validated tools. AI enables integration of Real-world (RWD) and multimodal data for improved treatment selection. To our knowledge, I3LUNG (NCT05537922) is the largest international trial building AI-based Physician Decision Support Systems (PDSSs) to support immunotherapy decisions.

Methods: NSCLC patients across six EU/non-EU centers were divided into C1 (durvalumab, stage III), C2 (First line IO), and C3 (later-line IO). We included: RWD (246 expert-selected features), CT_scans via PyRadiomics and Foundation Models (FMs), histopathology slides via FMs, and genomics (EGFR, ALK, ROS1, RET, STK11, KRAS, TP53). Endpoints were: primary, OS survival, death at OS<6 and ³24 months; secondary: DCR, ORR, PFS, TTF. Combined C2,3 was used for the primary analysis. Models included machine learning early fusion (MLEF) and deep learning intermediate fusion (DLIF), using Leave-One-Center-Out CV. Models were benchmarked against single biomarkers and scores. Fairness, explainability, and clinical usability were assessed.



Results: 2365 advanced NSCLC patients were enrolled; C2,3 (n=2075; C2:1437; C3:638) formed the primary analysis. 2075 had RWD, 1723 genomic, 1634 CT scans, and 936 histopathology slides. 339 patients had data from all four modalities. MLEF in C2,3 achieved AUCs of 0.74±0.08, 0.73±0.06, and 0.75±0.06 for OS24, OS6, and DCR, respectively. DLIF results were in line. MLEF models trained on C2 only showed higher performance than C2,3 (AUC: OS24=0.82±0.07, OS6=0.79±0.07, DCR =0.78±0.06). OS by Cox Regression (Cindex) was 0.66±0.02 for C2,3 and better for C2 (0.70±0.05).

AI-Multimodal approaches outperformed AI-RWD only in PDL1≥50% (among C2,3) with MLEF-submodel, detecting poor survivors with AUC=0.86±0.08, compared to 0.61±0.13 for RWD-only. IO monotherapy multimodal model identified long survivors with AUC=0.86±0.08 versus RWD's 0.54±0.10, and DCR with AUC=0.80±0.07 versus 0.61±0.10, regardless of PDL1 expression. On the testset, MLEF models outperformed single biomarkers across all outcomes: in DCR, AUC=0.71 vs. NLR=0.59 (p<0.01) and AUC=0.72 vs. PDL1=0.53 (p<0.001). Results are in line with OS24 and OS6. Models performed consistently on the test set across outcomes regarding AUC and C-index. Over the external validation set, OS achieved C-index=0.64.

Conclusion: The I3LUNG-PDSS AI tool demonstrates superior performance compared to traditional biomarkers, marking a significant advancement in predicting treatment outcomes for NSCLC patients. In submodels, on specific cohorts, the importance of multimodal data emerges compared to RWD, providing significant insights, despite the reduced sample. A prospective validation is ongoing across current centers, incorporating comprehensive multiomics data assessing PDSS generalizability.

Introduction: Trophoblast cell surface antigen 2 (TROP2) has emerged as a therapeutic delivery target in non-small cell lung carcinoma (NSCLC). However, its use as a predictive biomarker by conventional immunohistochemistry (IHC) has proven challenging. Quantitative Continuous Scoring (QCS), a fully-supervised computational pathology algorithm, has demonstrated the ability to predict NSCLC patient response to a TROP2 targeting antibody-drug conjugate (ADC) by quantifying TROP2 protein expression on digitized IHC slides. This global, multi-center study aims to assess the impact of pathologists input on QCS analysis of TROP2 expression in NSCLC and to evaluate its reproducibility across real-world laboratory settings.

Methods: A total of 100 commercial samples of NSCLC were obtained for the study, stained using the research-use-only (RUO) TROP2 (EPR20043) IHC assay using a standard protocol on VENTANA BenchMark ULTRA staining platforms, and qualified using the TROP2 (EPR20043) NSCLC NMR RUO algorithm. 64 cases were selected to be analyzed with the algorithm by 9 global sites and 1 internal Roche laboratory (n=30 pathologists) using Navify digital pathology (Navify DP). Stained slides were scanned on VENTANA DP600 or DP200 slide scanners and images were uploaded into Navify DP. Following algorithm training, pathologists generated normalized membrane ratio (TROP2-NMR) scores using the TROP2 (EPR20043) NSCLC NMR RUO algorithm. To algorithm reproducibility, overall percent agreement (OPA), positive percent agreement (PPA) and negative percent agreement (NPA) were calculated between readers and across sites. An exploratory analysis of raw TROP2-NMR scores and related metrics among pathologists was also performed.

Reproducibility of TROP2 expression assessment using the TROP2 (EPR20043) NSCLC NMR RUO algorithm was high across both sites and readers (TABLE 1). Across all 10 sites, the algorithm demonstrated a PPA of 99.9% and a negative percent NPA of 100.0%, resulting in an OPA of 99.9%. When comparing the Roche laboratory with nine external sites, the PPA was 99.9% and the NPA was 100.0%, with an OPA of 99.9%. Among the 30 participating pathologists, reader-level agreement remained consistently high, with a PPA of 99.9%, an NPA of 100.0%, and an OPA of 99.9%.

Although TROP2 QCS requires pathologist input to accurately evaluate TROP2 expression in NSCLC tumor cells, and such intervention could introduce variability, our data demonstrate that the QCS assessment of TROP2 expression is highly reproducible across pathologists. Despite TROP2-NMR being a fully quantitative score, the consistency observed confirms the robustness of this fully-supervised approach in real-world settings.

Table 1

Between Sites		Case level mode status					
Site	Slide-Level TROP2 Status	Positive	Negative	Total	Measure [a]	% (n/N)	95% CI [b]
Overall (10 sites)	Positive	955	0	955	PPA	99.9 (955/956)	(99.7, 100.0)

Introduction: Brain metastases are common in patients with non-small cell lung cancer (NSCLC) and are associated with poor prognosis. We report a retrospective analysis of patients treated with Dato-DXd or docetaxel in the phase 3 TROPION-Lung01 trial (NCT04656652) who had brain metastases at study entry, to assess the intracranial objective response rate (ORR) and intracranial progression-free survival (PFS).

Methods: Patients were randomized 1:1 to Dato-DXd 6 mg/kg or docetaxel 75 mg/m2 once every 3 weeks. All patients were required to undergo baseline brain imaging; those with asymptomatic brain metastases identified by the investigator (treated or newly discovered and stable at screening) were eligible for the study and were required to undergo further imaging assessments every 6 weeks. In this post hoc analysis (data cutoff: August 30, 2024), central nervous system (CNS) disease was retrospectively assessed by blinded independent central review (BICR) per CNS RECIST in the population with baseline brain metastases. Patients were divided into subgroups based on prior receipt of radiation. Those who received prior CNS radiation and subsequently experienced CNS progression before randomization were included in the untreated group. Patients were also further divided based on the presence or absence of measurable disease.

Results: Overall, 127/604 patients (21.0%) in TROPION-Lung01 had baseline brain metastases identified by CNS BICR (Dato-DXd, n=70; docetaxel, n=57). Baseline characteristics were balanced between treatment arms; 17 patients in each arm had EGFR mutations. Sixty-eight patients had untreated brain metastases/progression after radiotherapy (Dato-DXd, n=38; docetaxel, n=30); of these patients, 27 had measurable disease and 41 had non-measurable disease. In patients with untreated and measurable disease (n=27), the confirmed intracranial ORR in the Dato-DXd arm was 37.5% (95% CI, 15.2-64.6, including one complete response; n=6/16) and in the docetaxel arm was 0% (95% CI, 0-28.5; n=0/11). When including those with non-measurable disease, the confirmed intracranial ORR in the Dato-DXd arm was 15.8% (95% CI, 6.0-31.3; n=6/38) versus 0% (95% CI, 0-11.6; n=0/30) with docetaxel. All responses were observed in patients with nonsquamous histology, and outcomes in patients with EGFR-mutated tumors were consistent with the overall population. Median time to intracranial response to Dato-DXd was 1.5 months (range, 1.2-2.6; n=6); there were no responses in the docetaxel arm. Dato-DXd prolonged median intracranial PFS versus docetaxel in the overall population with baseline brain metastases (5.1 vs 4.4 months; hazard ratio [HR] 0.65 [95% CI, 0.39-1.09]; n=127) and in patients with untreated brain metastases/progression after radiotherapy (5.0 vs 3.0 months; HR 0.48 [95% CI, 0.23-0.98]; n=68).

Conclusions: In this retrospective analysis of TROPION-Lung01, Dato-DXd demonstrated intracranial activity and improved clinical benefit versus docetaxel in patients with baseline brain metastases, including those with untreated brain metastases or progression after radiotherapy. These findings were consistent with intracranial activity in the TROPION-Lung05 trial (NCT04484142), supporting the potential of Dato-DXd treatment in patients with NSCLC brain metastases.

OA10.02 Bevacizumab Plus Chemotherapy Versus Chemotherapy in Untreated Non-Squamous NSCLC With Brain Metastases: A Randomized, Phase 3 Study

M. Li[1], Y. Pan[1], G. Jiang[2], Q. Wang[3], G. Wu[4], W. Feng[5], S. Ma[3], X. Hou[1], L. Chen[1]
[1]sun yat-sen university cancer center, Guangzhou/CN ,[2]Southern Medical University Tenth Affiliated Hospital, Dongguan/CN ,[3]The Affiliated Cancer Hospital of Zhengzhou University, Zhengzhou/CN ,[4]Meizhou People's Hospital, Meizhou/CN ,[5]The First People's Hospital of Foshan, Foshan/CN

Introduction: There is a lack of prospective randomized controlled trials of antiangiogenic therapy in patients with brain metastases. We conducted this phase 3, randomized, multicenter study (BAP BRAIN) to evaluate the intracranial efficacy and safety of bevacizumab plus chemotherapy versus chemotherapy alone in patients with non-squamous non-small cell lung cancer (NSCLC) and brain metastases, and provide evidence for this previously unexplored subgroup.

Methods: Treatment-naïve, confirmed brain metastases and without sensitizing EGFR or ALK mutations, non-squamous NSCLC patients were screened from 11 centers in China. The eligible patients were randomly assigned (1:1) to receive bevacizumab plus pemetrexed-platinum or pemetrexed-platinum for 4-6 cycles, followed by bevacizumab plus pemetrexed or pemetrexed maintenance until disease progression, unacceptable toxicity or death. The primary endpoint was intracranial progression-free survival (iPFS), secondary endpoints included PFS, overall survival, intracranial objective response rate (iORR), systemic ORR and safety. We assessed efficacy and safety in the intention-to-treat population (all participants who received at least one dose of study treatment).

Results: Total 153 patients were enrolled and randomly assigned to receive bevacizumab plus pemetrexed-platinum (n=79) or pemetrexed-platinum (n=74). After a median follow-up of 16.8 months, the median iPFS was 11.07 months in bevacizumab plus chemotherapy group versus 5.73 months in chemotherapy group (HR=0.439, P<0.001). Similarly, the median systemic PFS was significantly longer in bevacizumab plus pemetrexed-platinum than pemetrexed-platinum alone (8.77 months versus 5.23 months, HR=0.540, P<0.001). Bevacizumab plus chemotherapy group had better iORR (69.6% versus 32.4%) and ORR (58.2% versus 27.0%) than chemotherapy group. The remission of cerebral edema was also higher in bevacizumab plus pemetrexed-platinum group (88.9% vs 34.9%). At the data cutoff, median OS was 28.07 months in bevacizumab plus pemetrexed-platinum group versus 18.53 months in pemetrexed-platinum group (HR=0.752, P=0.162). There was no ≥3 grade intracranial hemorrhage occurred, and most of adverse events were manageable.

Conclusions: This study demonstrated encouraging intracranial efficacy and acceptable safety of bevacizumab plus chemotherapy in patients with non-squamous NSCLC and brain metastases in the first-line setting.

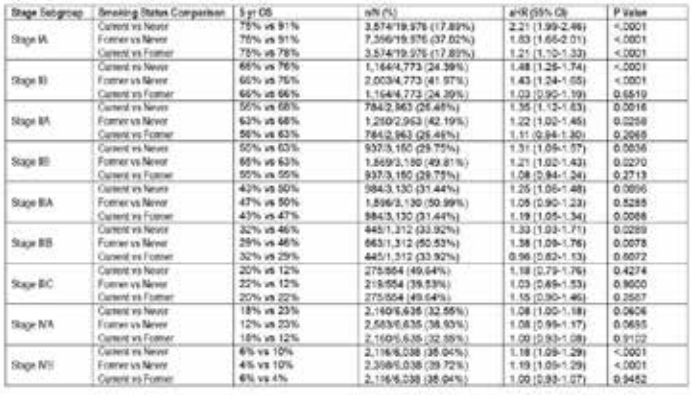
Introduction: Smoking is known to negatively impact lung cancer survival. Incorporating non-anatomical factors, such as the smoking history into staging may improve prognostication. We evaluated the impact of smoking status on the prognosis of patients with lung cancer.

Methods: Using the IASLC 9th edition NSCLC staging database, we evaluated the association between smoking status at diagnosis and overall survival (OS) using Kaplan-Meier curves and multivariable Cox proportional hazard models adjusted for age, region, sex, histological type, performance status and TNM stage. Subgroup analyses evaluated within- and between-stage survival according to smoking status. Recursive partitioning analysis evaluated the impact of smoking status relative to anatomical factors in staging.

Results: Among 48,531 patients with NSCLC, 26%, 41% and 34% currently, formerly or never smoked, respectively; 75% were diagnosed with adenocarcinoma and 21% with squamous cell carcinoma. Compared to those who never smoked, those who currently (aHR=1.39, 95% CI [1.34-1.46], p<0.0001) and formerly smoked (aHR=1.32, 95% CI [1.27-1.36], p<0.0001) had worse OS. Current smoking was also associated with worse OS (aHR=1.05, 95% [1.02-1.06], p=0.005) compared to former smoking. These associations were consistent within each stage group (Table 1). In pair-wise comparison, those who formerly or currently smoked had similar OS to patients in the next higher adjacent stage group who never smoked (Table 2). In patients with early-stage disease (up to T3N1M0), recursive partitioning analysis demonstrated that smoking status had greater prognostic impact than N0 vs N1 categories, while among patients with locally advanced (T4 or N2+) disease, smoking status still identified unique prognostic subgroups.

Conclusions: Smoking status is an important prognostic factor in this lung cancer staging cohort and may have greater impact on prognosis than some anatomical descriptors. Further exploration of combining smoking status and TNM classification for lung cancer is planned in the 10th edition IASLC staging project.



Stage Subgroup	Smoking Status Comparison	5 yr OS	n/N (%)	aHR (95% CI)	P Value

Introduction: TNM staging systems create prognostic categories by anatomic extent of disease. Whether therapeutically important molecular alterations in NSCLC augment the prognostic information of TNM staging is unclear. To study this, we analyzed molecular data from the 9th edition of the lung cancer staging system.

Methods: Eligible patients were diagnosed between 2011-2019. Analysis was restricted to three genes for reliable statistical analyses: EGFR mutations (L858R, exon 19 deletion), ALK fusions, and KRAS mutations (codons 12, 13, or 61). Overall survival (OS) was calculated by the Kaplan-Meier method and differences in OS assessed by Cox proportional hazard regression models.

Results: 20,580 patients had tumors with molecular data (EGFR = 16,497, ALK = 11,546, KRAS = 2,909 patients). EGFR mutations were found in 5,428 (32.9%), ALK fusions in 723 (6.3%) and KRAS mutations in 890 (30.6%) tumors. OS was significantly better across all TNM stages among patients with EGFR mutated tumors and patients with Stage IV ALK fusion-positive tumors, while patients with Stage I KRAS mutated tumors had significantly worse OS. Multivariable analyses confirmed the OS associations with EGFR mutated tumors (Stage I HR = 0.79, Stage II HR=0.71, Stage III HR = 0.67, Stage IV HR = 0.49) and stage IV ALK fusion-positive tumors (HR = 0.56).

Conclusions: Patients with EGFR mutated tumors had improved OS regardless of stage while an OS benefit was seen in stage IV patients with ALK positive tumors. In the 10th edition, we will systematically integrate molecular biomarkers and treatment to refine prognostication for molecular subsets of NSCLC.

OA11.03 The Survival Impact of Subdividing Clinical and Pathologic N2 Descriptors in a Population-Based Surgical Cohort

J. Rice[1], M.P. Smeltzer, PhD[1], O. Akinbobola, MPH[2], C. Fehnel, BBA, CCRP[2], A. Saulsberry, DBA[2], K. Dortch, BS[2], C.E. Soma, MPH[1], M.A. Ray, PhD[1], R. Osarogiagbon, MBBS, FACP[2]
[1]Division of Epidemiology, Biostatistics, and Environmental Health, University of Memphis School of Public Health, Memphis/TN/USA ,[2]Thoracic Oncology Research Group, Multidisciplinary Thoracic Oncology Program, Baptist Cancer Center, Memphis/TN/USA

Introduction: The 9th edition lung cancer staging system subdivided the N2 category based on single station (N2a) and multi-station (N2b) ipsilateral lymph node involvement. We assessed the prognostic value of this revision in a population-based US cohort.

Methods: We analyzed patients in the Mid-South Quality of Surgical Resection (MSQSR) cohort from 2009-2024. We retrospectively reclassified N2 descriptors based on single vs multiple station lymph node (LN) involvement. We compared overall survival (OS) with the log-rank test and fit proportional hazards (PH) models with crude and adjusted hazard ratios (aHR). Adjusted models included age, sex, histology, smoking status, comorbidities, and adjuvant therapy.

Results: Of 4363 eligible patients (median follow-up 44 months), the relative proportions of N2 were 120 (78%) cN2a versus 34 (22%) cN2b; and 259 (75%) pN2a versus 83 (25%) pN2b. In both crude and adjusted analysis, OS differed significantly between pN2a and pN2b (aHR: 1.47, p=0.02, Figure 1B) but not for cN2a and cN2b (aHR: 1.35, p=0.19, Figure 1A). Additionally, OS was significantly better in pN1 vs. pN2a (aHR: 1.28, p=0.01), but not for cN1 vs. cN2a (aHR: 1.01, p=0.92). A sensitivity analysis among patients meeting CoC Operative Standard 5.8 found significant differences in OS in pN2a vs. pN2b (aHR: 1.86, p<0.01) but not pN1 vs. pN2a (aHR: 1.39, p=0.06) or cN2a vs. cN2b (aHR:1.02, p=0.96). Sensitivity analyses for patients with PET scans revealed significant associations between pN2a and pN2b in adjusted models (aHR: 1.50, p=0.02) as well as among those with at least 6 LNs sampled (aHR:1.47, p=0.02). Neither sensitivity analysis showed significant results for cN2a vs cN2b (aHR:1.23, p=0.41 for PET and aHR:1.29, p=0.43 for at least 6 LNs sampled).

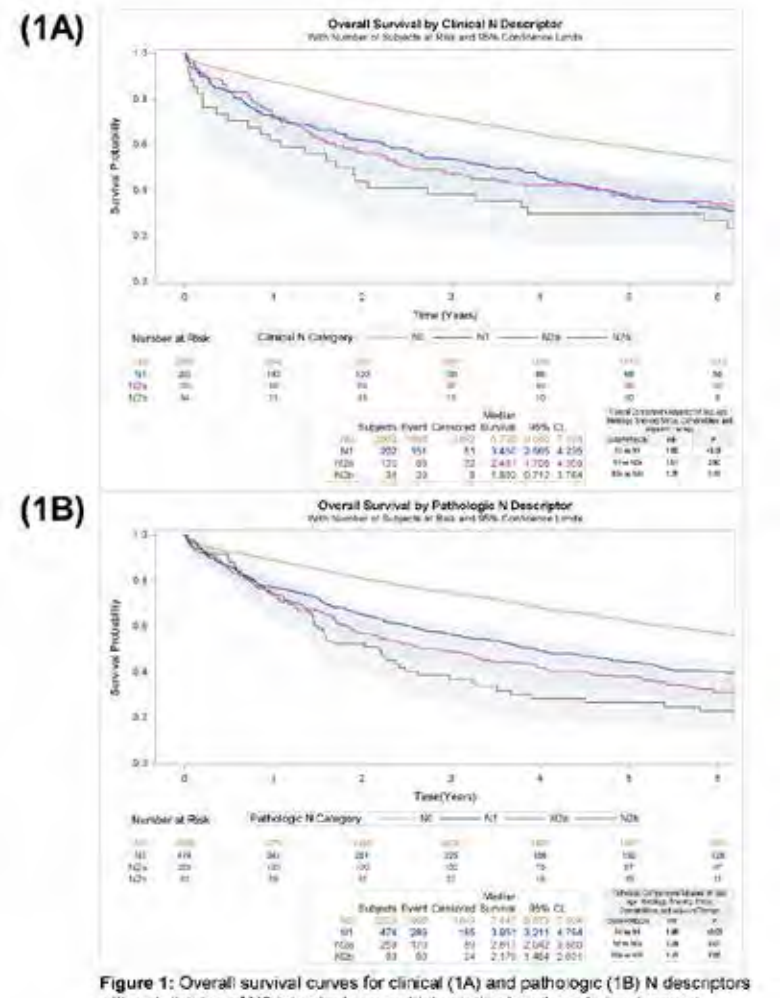

Figure 1: Overall survival curves for clinical (1A) and pathologic (1B) N descriptors with subdivision of N2 into single vs multiple station lymph node involvement.

Conclusions: The pN2, but not the cN2, subdivision was significantly associated with overall survival in this population-based cohort. Our inability to discriminate between cN2a and cN2b could be explained by the relatively small sample size or preoperative staging limitations.

OA11.04 Validation and Refinement Proposal of the Ninth Edition n Descriptor for Non-Small Cell Lung Cancer Receiving Neoadjuvant Therapy

H. Si[1], L. Xu[1], Y. Dong[1], J. Yu[1], M. Yang[2], X. Li[3], J. Fan[4], J. Wu[1], H. Xie[1], C. Chen[1]
[1]Shanghai Pulmonary Hospital, Shanghai/CN ,[2]Ningbo No. 2 Hospital, Ningbo/CN ,[3]Ningbo Hospital, Zhejiang University, Ningbo/CN ,[4]The Second Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, Zhejiang/CN

Introduction: Although the ninth edition N descriptors have been validated in upfront surgery populations, evidence supporting their validity and addressing their limitations in prognostic stratification in the neoadjuvant setting remain sparse. The study aimed to validate these newly proposed N descriptors, and explore the prognostic relevance of exploratory quaternary N scheme relative to the ninth edition N classification in postneoadjuvant non-small cell lung cancer (NSCLC).

Methods: We identified 1,005 NSCLC individuals who underwent complete resection following neoadjuvant therapy from four clinical centers between May 2019 and September 2022. Prognostic difference of adjacent N categories' comparison regarding recurrence-free survival (RFS) and overall survival (OS) was estimated by the log-rank test and the Cox proportional hazards model. Decision curve analysis (DCA) was performed to quantify incremental survival prediction benefit.

Results: According to the ninth edition proposal, pathologic N0, N1, N2a, and N2b were associated with a stepwise deterioration in prognosis, except between N1 and N2a (p=0.331 for OS; p=0.508 for RFS, Figure 1A). In exploratory analyses, multiple N1 stations involvement subcategory (N1b) with N2a showed prognostic homogeneity and comparable adjuvant treatment benefit (Figure 1B). With observed homogeneity, integration of N1b and N2a into one single group could significantly distinct from single N1 station involvement (N1a) (p=0.019 for OS; p=0.018 for RFS) as well as from N2b (p<0.001 for both OS and RFS, Figure 1C). Sensitivity analyses stratified by neoadjuvant regimen, histology, and T descriptor revealed that exploratory four-tier N scheme similarly exhibited a graded tendency towards prognostic decline. Further DCA indicated exploratory quaternary descriptors comprising of N0/N1a/N1b+N2a/N2b yielded stronger prognostic relevance than the ninth edition classification (Figure 1D).

Conclusions: The ninth edition N classification was validated to demonstrate moderate prognostic discrimination in neoadjuvant population. Exhibiting superior prognostic stratification, burden-directed and location-supplemented N considerations would provide novel insights into further N refinement.

OA12.01 IASLC Mesothelioma Staging Project: Impact of Molecular Alterations on Survival in a Cohort From 9Th Edition Database

J.L. Sauter[1], M.Y. Tjota[2], S-R. Yang[1], E. Goren[3], D.J. Giroux[3], R. Aly[1], M.W. Drazer[2], F. Galateau-Salle[4], A.N. Hussain[2], H. Kindler[2], K. Lechtenberg[5], W.D. Travis[1], V.W. Rusch[1], M. Tsao[6]
[1]Memorial Sloan Kettering Cancer Center, New York/NY/USA ,[2]University of Chicago, Chicago/IL/USA ,[3]Cancer Research And Biostatistics, Seattle/WA/USA ,[4]MESO BANK, Lyon/FR ,[5]International Association for the Study of Lung Cancer, Denver/CO/USA ,[6]Princess Margaret Cancer Centre, Toronto/ON/CA

Introduction: The current staging system for pleural mesothelioma (PM) is based on anatomic extent of disease. Whether assessment of molecular alterations adds prognostic information is undefined. We examined the impact of molecular alterations on overall survival (OS) in PM in a 3-institution cohort from IASLC 9th edition Staging Project.

Methods: Biomarker data included PD-L1 IHC (clones E1L3N, 28-8, or 22C3), BAP1 IHC, and somatic NGS. BAP1, CDKN2A, and NF2 genes were categorized as wild-type (WT), pathogenic, or variant of unknown significance (VUS). TP53 mutational status was categorized as WT or pathogenic. OS was calculated from date of diagnosis by Kaplan-Meier method and compared between groups by Cox proportional hazard regression. Hazard ratios for pathogenic alterations were adjusted for age, sex, histology, performance status, curative-intent resection (EPP or EPD), and TNM categories. Models were compared using pseudo-R2 and Harrell's C-statistic.

Results: The cohort included 556 patients: median age=72 years; 72.7% male; 77.5% epithelioid; 69.6% cT1-T3, cM0 stage; 29.3% curative-intent resection; 82.0% treated with systemic therapy. Pathogenic alterations in BAP1 were most common (141/262, 53.8%), followed by CDKN2A (94/262, 35.96%), NF2 (62/262, 23.7%) and TP53 (47/262, 17.9%). Loss of BAP1 by IHC was detected in 58.2% (263/452) of cases. PD-L1 expression by IHC was positive (> 1% membranous staining) in 43.7% (69/158) and 47.6% (20/42) of epithelioid and non-epithelioid PM cases, respectively. Median OS for entire cohort (n=556) was 19.1 months. On univariate analysis, pathogenic alterations in CDKN2A (HR 2.67, CI: 1.93-3.69), NF2 (HR 1.89, CI: 1.34-2.67), and TP53 (HR 1.86, CI: 1.27-2.73) were associated with worse OS (p<0.001), while BAP1 alterations were associated with better OS (NGS HR 0.63, CI: 0.46-0.85, p=0.003; IHC HR 0.60, CI: 0.48-0.75, p<0.001). PD-L1 IHC expression was not associated with OS (p=0.645). Multivariable analyses confirmed OS associations. While the clinical covariates performed better than the set of molecular alterations alone (C-statistic: 0.67 vs 0.65; R2: 25.8 vs 20.2), a model that included BAP1 alterations plus any pathogenic alteration in CDKN2A, NF2, and TP53, along with clinical covariates best predicted survival (C-statistic: 0.70; R2: 37.1).

Conclusions: In this large, clinically well-annotated cohort, alterations in CDKN2A, NF2, and TP53 were associated with worse OS, while BAP1 alterations were associated with better OS in PM independent of clinical variables and histology. Modeling suggests that genomic alterations provide additional prognostic information beyond anatomic TNM and pathologic features. These findings will be studied further in the 10th edition database.

Table. Somatic next generation sequencing results in pleural mesothelioma.

	Total (N=262)
BAP1, n (%)	
Altered: pathogenic	141 (53.8%)
Altered: VUS	6 (2.3%)
Wild type	115 (43.9%)
CDKN2A, n (%)	
Altered: pathogenic	94 (35.9%)
Altered: VUS	1 (0.4%)
Wild type	167 (63.7%)
NF2, n (%)	
Altered: pathogenic	62 (23.7%)
Altered: VUS	3 (1.1%)

Introduction: IND227 was a 3-arm randomised phase 2 trial that was amended to a 2-arm phase 2/3 design. The final phase 2/3 analysis revealed improved overall survival (OS) with the addition of pembrolizumab to standard platinum-pemetrexed chemotherapy in advanced incurable pleural mesothelioma (PM), with a hazard ratio (HR) for OS of 0.79 [95 % CI 0.64-0.98, log-rank p=0.0324]. Herein we present the final, updated OS analysis along with additional exploratory analyses.

Methods: Fit, eligible adult patients with advanced, incurable PM were enrolled at sites in Canada, Italy and France. IND227 was originally designed as a 3-arm phase 2 trial with a primary endpoint of progression-free survival, in which patients were randomized 1:1:1 (stratified by histology) to standard platinum (either cisplatin or carboplatin) and pemetrexed chemotherapy q3weeks for up to six cycles with or without the addition of pembrolizumab 200 mg q3weeks for up to two years, or to pembrolizumab alone [J Thorac Oncol 2023;18:813-819]. At the first planned interim analysis (2017), the CCTG DMSC recommended the pembrolizumab cohort be discontinued. In 2018, the trial was amended to a phase 2/3 trial in which patients were randomized 1:1 to chemotherapy +/- pembrolizumab with a primary endpoint of OS. Patients included in the first interim phase 2 analysis (phase 2 only cohort) were excluded from the final analysis of the phase 2/3.

Results: A total of 440 patients were included in the phase 2/3 final analyses; 222 randomized to chemotherapy+pembrolizumab and 218 to chemotherapy alone. Median age 71 years (range 28-88), 24% female, 78% epithelioid, 47 % PS 0. At the updated phase 2/3 analysis (data cut-off September 30, 2023), with a median follow up of 16.2 months (range 0.03-69.9), an additional 29 deaths had occurred. The HR for OS was 0.79 [0.64-0.97, nominal p = 0.022]. The estimated 3- and 5-year survivals were 24 and 12 % with the addition of pembrolizumab versus 18 and 2 % for chemotherapy alone. For the epithelioid subgroup, the HR for OS was 0.85 [0.67-1.08] and for the non-epithelioid subgroup was 0.65 [0.42-1.00].

Conclusions: The benefit of the addition of pembrolizumab to standard chemotherapy in advanced PM is confirmed with longer follow-up. Additional analyses, including outcomes by biomarkers such as BAP1, and exploratory analyses incorporating additional patients enrolled to the phase 2 component of the trial [phase 2 only cohort; n=80] originally excluded from the OS analysis will be presented at the meeting. Central pathology re-review is also planned.

[1]Johns Hopkins Sidney Kimmel Comprehensive Cancer Center, Baltimore/MD/USA ,[2]The University of Texas MD Anderson Cancer Center, Houston/TX/USA ,[3]Fox Chase Cancer Center, Philadelphia/PA/USA ,[4]Swedish Medical Center, Englewood/CO/USA ,[5]Queen's University, Kingston/ON/CA

Introduction: While the role of surgery in limited-stage diffuse pleural mesothelioma (DPM) is controversial, an aggressive tri-modality approach incorporating perioperative chemotherapy (CT), surgery, and radiotherapy (RT) is considered for select patients. Immune checkpoint blockade (ICB) has shown a survival benefit in advanced DPM, but its role in perioperative management of DPM is unclear. This prospective, multi-center, multi-arm clinical trial investigated neoadjuvant nivolumab (nivo) and nivolumab/ipilimumab (nivo/ipi) in patients with resectable DPM (NCT03918252).

Methods: Patients with epithelioid or biphasic DPM deemed resectable by multidisciplinary assessment were enrolled sequentially to receive neoadjuvant nivo 240mg IV every 2 weeks (q2w) for 3 doses (Arm A) or nivo 3mg/kg IV q2w for 3 doses with ipi 1mg/kg given on day 1 only (Arm B). After surgery, patients received optional adjuvant RT and/or CT followed by nivo 480mg IV q4w for 1 year. Co-primary endpoints were safety (frequency of dose-limiting toxicities [DLTs]) and feasibility (proportion of surgeries occurring ≤24 days from the preplanned surgery date), with feasibility defined by a posterior 90% credible interval (pCI) encompassing 80%. Key secondary endpoints included event-free survival (EFS - time from neoadjuvant therapy initiation to progression precluding surgery, recurrence post-surgery, or death) and overall survival (OS - time from neoadjuvant therapy initiation to death).

Results: 30 patients (16 Arm A, 14 Arm B) were enrolled and received neoadjuvant ICB. In Arm A, median age was 64 years, 81.3% (13/16) were male, and 87.5% (14/16) had epithelioid histology (2/16 had biphasic histology). In Arm B, median age was 68 years, 57.1% (8/14) were male, and 78.6% (11/14) had epithelioid histology (3/14 biphasic). In Arms A and B, surgery was performed in 81.3% (13/16) and 78.6% (11/14) of patients, of which 11/13 and 11/11 completed surgery within the predefined feasibility window, respectively. The posterior means and pCIs for feasibility were 67.0% (90% pCI: 47.8-83.4) and 75.0% (90% pCI: 56.0-90.3) in Arms A and B, respectively. One DLT was seen in each arm (pneumonitis - Arm A; elevated ALT - Arm B), neither precluded surgery. Among the 13 patients who completed surgery in Arm A, 9 (69.2%), 7 (53.9%), and 7 (53.9%) received adjuvant CT, RT, and nivo, respectively. Of the 11 patients who completed surgery in Arm B, 5 (45.5%), 5 (45.5%), and 5 (45.5%) received adjuvant CT, RT and nivo, respectively. At median follow-up of 43.2 months in Arm A, the median EFS and OS were 9.6 months (95% confidence interval (CI): 2.5-27.7) and 19.3 months (95% CI: 14.9-34.7), respectively. At median follow-up of 21.5 months in Arm B, the median EFS and OS were 19.8 months (95% CI: 5.5-not reached [NR]) and NR (95% CI: 20.4-NR), respectively.

Conclusions: Incorporation of neoadjuvant ICB into the perioperative treatment of limited-stage DPM was safe and feasible, without delay of resection. Compared to historical data with systemic therapy alone, neoadjuvant nivo/ipi demonstrated favorable long-term clinical efficacy. Planned correlative analyses will explore immunologic, molecular, and pathologic features of response in order to identify patient subsets most likely to benefit from this approach.

Introduction: We developed a new treatment paradigm for pleural mesothelioma using accelerated sub-ablative hemithoracic radiotherapy (hemi-RT) with concomitant boost followed by surgery one week later. This approach demonstrated encouraging results in epithelioid mesothelioma in the SMART trial using hemi-RT dose of 25Gy/5 daily fractions followed by extrapleural pneumonectomy. The safety of hemi-RT before lung-sparing surgery was demonstrated in the SMARTER trial using hemi-RT dose up to 12 Gy/3 alternate daily fractions. In this analysis, we performed correlative studies to define the mechanisms of immune activation after radiation, and to identify potential biomarkers predicting response.

Methods: Tumor samples from patients treated with the SMART (n=48) and SMARTER approach (n=24) were analyzed using single-cell RNA sequencing, CyTOF, transcriptomics (Nanostring), and multiplexed imaging mass cytometry. Luminex was performed in the serum collected before radiation, at the time of surgery (9±2 days post-RT), and during follow-up (6±2 weeks post-surgery) in the SMARTER trial (n=24). Homozygous deletion of CDKN2A/p16 (p16HD) was defined by FISH, and BAP1 loss by immunohistochemistry.

Results: Circulating CXCL10, FLT3L, and IL-5 significantly increased post-RT. Persistent CXCL10 upregulation post-surgery was associated with longer OS, independent of tumor histology, tumor volume, nodal disease, T category, and BAP1 loss in multivariate analysis. CXCL10 upregulation post-RT was detected in CDKN2A/p16 wild type (p16WT) tumors, and inversely correlated with its baseline level (r=-0.53, p=0.006). At baseline, epithelioid p16WT tumor cells were characterized by a type-I interferon (IFN-I) response associated with VSIR (VISTA) upregulation, and an immunosuppressive TME generated by VSIG4+ tumor associated macrophages (TAMs). BAP1 loss was associated with downregulation of the stimulator of IFN genes, TMEM173 (STING), specifically in tumor cells compared to BAP1 WT. p16HD tumor cells were characterized by a cancer-associated fibroblast (CAF)-like phenotype expressing TNFA-signaling, and promoting an inflammatory TME. Radiation induced CDKN1A/p21 in epithelioid p16WT tumor cells, promoting an adaptive immune response with upregulation of CXCL10 and SLAMF7 in TAMs, and reinvigoration of cytotoxic CD8+ T cells. The immune response was predominantly mediated by an IFN response in tumors with BAP1 loss, and TNFA-signaling in BAP1 WT. The potential benefit from sub-ablative hemi-RT and surgery in epithelioid p16WT mesothelioma was retrodicted in the SMART trial with DFS and OS reaching 54% and 60% at 5 years, respectively. The benefit was particularly notable in epithelioid p16WT mesothelioma with BAP1 loss, reaching a DFS of 60% and OS of 70% at 5 years. The best OS correlated with upregulation of SLAMF7 (r=0.81, p=0.0008) and CXCL10 (r=0.73, p=0.004). CDKN1A/p21+ tumor cells interacted with CAFs to promote EMT, and suppress the IFN response in non-epithelioid mesothelioma. Radiation, paradoxically, upregulated IFN-stimulated genes in p16HD tumor cells, and suppressed the TME.

Conclusions: These results demonstrated the potential benefit of radiation in epithelioid p16WT mesothelioma. BAP1 loss was associated with the downregulation of STING in tumor cells, and greater activation of the adaptive immunity after radiation. By deciphering the mechanisms of response to radiation at a molecular level, we identified divergent TME with different responses to therapy, providing a rationale for more personalized therapy in mesothelioma.

Introduction: BNT327 (pumitamig) is an investigational bispecificantibody targeting PD-L1 and VEGF-A, designed to restore effectorT-cell function through PD-L1 binding while co-localizing VEGF-A neutralizationwithin the tumor microenvironment. Pumitamig+chemotherapyshowed encouraging activity in Phase 2 trials in Chinesepatients with SCLC. Hereinwe present the first pumitamig data from a global population.

Methods: In this global Phase 2, randomized, open-label,parallel group trial (NCT06449209), patients with treatment-naïveES-SCLC received pumitamig+etoposide+carboplatin x 4 cycles followed by pumitamigmaintenance (Cohort 1); patients progressing after 1L or 2L treatment received pumitamig+paclitaxel(Cohort 2) or pumitamig+topotecan (Cohort 3). Patients within each cohort wererandomized to pumitamig 20 or 30 mg/kg IV Q3W for up to 2 years or untildisease progression/unacceptable toxicity. Primary endpoints were efficacy perRECIST 1.1 (ORR per investigator, change in tumor size and early tumorshrinkage) and safety per NCI CTCAE v5.0.FoundationOne®Liquid CDx analysis estimated circulating tumorfraction (TFx) of cell-free DNA (cfDNA). Here wepresent data from Cohort 1 supporting optimal dose finding for Phase 3development.

Results: At cutoff (04 Apr 2025), enrolment wascomplete with 107 patients. In Cohort 1 (N=43median age: 65.0 years [range 45-80], 62.8% ECOG PS 1; median pumitamigtreatment duration: 11.6 weeks), 22 patients received pumitamig 20 mg/kg and 21received 30 mg/kg. Amongst 38 efficacy-evaluable patients, 33 had PR and 5 had SDresulting in 86.8% unconfirmed ORR (uORR) and 100% DCR. The mean bestpercentage change in tumor size was -47.3%with 89.5% of patients achieving early tumor shrinkage. uORR was 95.0%and 77.8% with pumitamig 20 mg/kg and 30 mg/kg, respectively. Among 11 patients with 2 post-baseline tumor assessmentsand >90 days' follow-up, confirmed ORR was 81.8% (9/11) for both dose levels,and 100% (6/6) for 20 mg/kg and 60.0% (3/5) for 30 mg/kg; DoR and PFS were notmature. Updated efficacy, including early DOR and PFS, will bepresented.Baseline circulating tumor DNA (ctDNA) detection ratewas 93.8% (30/32 patients with cfDNA data), with median TFx of 57.0%. At C3D1,all evaluable patients (n=18) had confirmed ctDNA reduction vs baseline, with amedian TFx change of -99.3% and ctDNA clearance rate of 44.4% (8/18). Similarresults were observed between dose levels. Adverseevents (AEs) related to any treatment were reported in 35/43 (81.4%) patientsand were Grade ≥3 in 23 (53.5%) patients. Pumitamig-related Grade ≥3 AEs were reported in 1 patient receiving 20 mg/kg and 5receiving 30 mg/kg (hypertension [n=2], platelet count decreased, hemoptysis,proteinuria, and pulmonary embolism [n=1 each]). Six (14.0%) patients discontinuedpumitamig due to AEs (20 mg/kg n=2, 30 mg/kg n=4). Notreatment-related deaths occurred.

Conclusions: Pumitamig plus etoposide/carboplatinshowed encouraging efficacy and acceptable safety in 1L ES-SCLC. This firstpresentation in a global population of a bispecific antibody targetingcheckpoint inhibition and angiogenesis confirms the encouraging data previouslyreported in the 1L SCLC Chinese study (https://doi.org/10.1016/S1556-0864(25)00494-0).This dose optimization study supportsfurther development of pumitamig in 1L SCLC,currently being evaluated in the ROSETTA Lung-01 Phase 3 trial.

Introduction: RYZ101 (225Ac-DOTATATE) is a first-in-class, alpha-emitting radiopharmaceutical in development for the treatment of patients with somatostatin receptor-expressing (SSTR2+) solid tumors. Alpha particles (emitted by 225Ac) have a higher linear energy transfer (80-100 keV/µm) and shorter path length (40-100 µm) than beta particles, potentially allowing for improved cancer cell kill rates while limiting off-tumor toxicity. Here we describe preliminary safety data from a single-arm, open-label, phase 1b dose-escalation and dose-expansion trial of RYZ101 in combination with standard of care (SoC) therapy in patients with treatment-naïve SSTR2+ extensive-stage small-cell lung cancer (ES-SCLC; NCT05595460).

Methods: Adult patients with histologically/cytologically confirmed SSTR2+ ES-SCLC, ECOG PS 0-1, life expectancy ≥12w, and sufficient renal, hepatic, and hematologic function are eligible. Patients must have ≥1 SSTR2 PET imaging-positive RECIST v1.1-measurable disease sites; ≥50% of measurable lesions must be SSTR2+. Patients may receive ≤1 cycle of SoC before/during screening. Patients with CNS metastases are permitted but must be asymptomatic, adequately treated, and on stable/decreasing steroid doses. During dose-escalation, patients receive RYZ101 (IV q6w then q4w) starting at dose level 1 (DL1) of 6.5 MBq, with escalation to 8.3 MBq (DL2) and 10.2 MBq (DL3) in the absence of dose-limiting toxicities (DLTs). Patients also receive SoC: atezolizumab (Tecentriq®, 1200 mg IV d1 q21d ≤4 cycles, then 1680 mg IV q28d); carboplatin (AUC 5-6 IV 60min d1 q21d ≤4 cycles); etoposide (80-100 mg/mm2 IV 60min d1-3 q21d ≤4 cycles). Primary endpoints: safety, recommended phase 2 dose. Secondary endpoints: efficacy, pharmacokinetics.

Results: Forty-three patients have been screened and 15 have been dosed with RYZ101 to date. As of September 3, 2024, nine patients (n=4; DL1 and n=5; DL2) had mature safety data. Median age was 67 years (range 49-79), 55.6% were female, and 88.9% were former smokers. All patients received 1 cycle of SoC before/during screening. Median treatment duration of RYZ101 was 2.9 months (range 1.4-11.9); median number of RYZ101 doses was 2.0 (range 1-6). Treatment is ongoing in five patients (DL2). No DLTs were reported. One patient had a G≥3 RYZ101-related AE (DL1; G4 lymphocyte count decreased). Other RYZ101-related AEs occurred in three additional patients: G1 diarrhea, eosinophilia, fatigue, and vomiting (all n=1); and G2 decreased appetite, dehydration, depression, fatigue, influenza-like illness, nausea, neutrophil count decrease, and weight decreased (all n=1). SAEs, all unrelated to RYZ101, were pneumonia (n=2), and infective arthritis, sepsis, pain, back pain, hyponatremia, spinal cord compression, and syncope (all n=1). One patient had G4 neutropenia related to SoC following 3 cycles of SOC and 1 of RYZ101 requiring temporary RYZ101 dose reduction; this recovered with dose delays and supportive care.

Conclusions: There were no DLTs reported at DL1 (6.5 MBq) or DL2 (8.3 MBq) and the RYZ101 dose was escalated to DL3 (10.2 MBq) with six patients dosed to date; the study has completed enrollment for dose escalation and is proceeding to dose expansion. Updated data will be presented.

Introduction: The World Health Organization (WHO) classifies pulmonary carcinoids (well-differentiated neuroendocrine tumors or NETs) as typical carcinoids (grade 1; <2 mitoses per 2 mm2) and atypical carcinoids (grade 2; 2-10 mitoses per 2 mm2 and/or necrosis). Lung tumors with carcinoid/NET morphology but exceeding 10 mitoses per 2 mm2 are rare, and are currently classified in the WHO as large cell neuroendocrine carcinoma (LCNEC); however, this has been a matter of growing debate. To address this, the IASLC Pathology Committee initiated a multi-institutional study to collect and characterize such tumors with the goal of clarifying their clinicopathologic characteristics and optimal classification.

Methods: Members of the Neuroendocrine Working Group within the IASLC Pathology Committee identified resected lung tumors meeting the inclusion criteria (carcinoid morphology with mitotic count of >10/2mm2) from their individual institutions. Digitized whole-slide images were organized and reviewed using PathPresenter, including H&E and immunohistochemistry (IHC) for Ki67, neuroendocrine markers (synaptophysin, chromogranin, INSM1, CD56), pRb, and p53. Detailed clinicopathologic characteristics and clinical outcome data were analyzed. Areas of highest (hot-spot) and lowest (cold-spot) Ki67 proliferation index were assessed by digital image analysis with >500 cells counted in triplicate. Available results of next-generation sequencing (NGS) were reviewed.

Results: A total of 27 cases from 9 institutions in 7 countries were collected that met the criteria of tumors with morphology of carcinoids/NETs (confirmed by central review) and mitoses of >10 per 2 mm2. Patients were 52% female with a mean age of 63, and 40% were never/light (<10 pack-year) smokers. All tumors were strongly and diffusely positive for all neuroendocrine markers. Mitotic counts ranged from 11 to 30 (mean 15 per 2 mm2). In most cases, mitotic counts remained below 20, with only 3 cases exceeding 20 per 2 mm2. Ki67 hot-spot index ranged from 16% to 56% (mean 34%), with 4 cases exceeding 50%. However, in all cases, Ki67 was heterogenous, containing low-proliferative cold-spots where Ki67 index was only <1%-10%. In all evaluable cases (n=25), pRb and p53 showed retained expression or focal labeling, respectively, supporting a wild-type pattern. Cases with NGS (n=6) lacked RB1 and TP53 alterations, and contained MEN1 (n=1) and ATM (n=1) mutations, which are common in carcinoid tumors. For patients with available follow-up (n=21), 62% had post-operative recurrence/metastasis within a median follow-up of 2.7 yrs (range 0.3 -10 yrs).

Conclusions: In this multi-institutional international study, we collected the largest cohort to-date of rare resected pulmonary tumors with carcinoid/NET morphology but proliferation rates exceeding current WHO criteria. We highlight here that while elevated, mitotic and Ki67 rates are generally lower and more heterogenous than typically seen in LCNEC or small cell lung carcinoma (SCLC), and these tumors lack TP53+/-RB1 alterations seen in most SCLC/LCNEC. We propose that such tumors should be classified as highly proliferative, grade 3 (G3) carcinoids/NETs, analogous to G3 NETs recognized in enteropancreatic organs, and that they should be removed from their current grouping as LCNEC to enable clinical management that is more accurately tailored to tumor biology.

OA14.01 Glutamine Metabolic Reprogramming Drives Evolution of Lung Adenocarcinoma

Y. Wang, S. Li, X. Liu, C. Chen
shanghai pulmonary hospital, shanghai/CN

Introduction: Lung adenocarcinoma represents the predominant pathological subtype of lung cancer, progressing from precursor non-invasive lesions to invasive adenocarcinoma (IA). Glutamine (Gln) metabolism reprogramming stands as a significant biological hallmark in lung cancer, yet its exact contribution to LUAD progression remains unclear.

Methods: We performed spatial metabolomics on lung tissue obtained from patients with lung adenocarcinoma (n = 76). We validated these data using immunofluorescence on lung tissue from 24 additional subjects. Organoid, western blotting, quantitative PCR, invasion and migration analysis were applied to assess differentiation, invasion, and migration in vitro and in vivo.

Results: Preliminary spatial metabolomics analysis revealed enhanced Gln extramitochondrial metabolism in the invasive focus of IA. Further studies identified tumor-initiating cells (TICs) as effectors of Gln metabolism, with high expression of glutamic-oxaloacetic transaminase 2 (Got2) promoting extramitochondrial Gln metabolism and glutathione generation, regulating the redox homeostasis within TICs and promoting their invasive differentiation. Mechanically, small ubiquitin-like modifier (SUMO) modification of Nr5a2 promotes Got2 transcription, enhancing extramitochondrial Gln metabolism within TICs, regulating intracellular redox homeostasis, activating invasive differentiation of TICs, and driving the invasive progression of lung adenocarcinoma.

Conclusions: Our study depicts the metabolic landscape of lung adenocarcinoma progression using multi-omics data and elucidates the metabolic mechanisms driving the progression of lung adenocarcinoma in vitro and in vivo, providing new therapeutic targets for this malignancy.

OA14.02 DCBLD2high Tumor-Derived Retinoic Acid Orchestrates Macrophages to Drive Vascular Immunosuppression and Immunotherapy Resistance

S. Li, Z. Dong, W. Wang, X. Bai
Nanfang Hospital, Southern Medical University, Guangzhou/CN

Introduction: Immunotherapy resistance represents a critical challenge in the management of lung cancer. While tumor angiogenesis is increasingly recognized as a driver of immunosuppression in the tumor microenvironment (TME), the molecular mechanisms linking vascular remodeling to immune evasion remain elusive, and targeted therapeutic strategies to disrupt this crosstalk have yet to be clinically implemented.

Methods: To identify master bipotent regulators of angiogenesis and immunosuppression in lung cancer, we performed WGCNA network analysis on CPTAC and TCGA transcriptomic data. Top candidates were validated through multi-omics (Single-cell sequencing, spatial proteomics, and bulk RNA-seq) to define their roles in shaping the immunosuppressive TME. Furthermore, an immune system-tumor double humanized lung cancer patient-derived xenograft (PDX) models were established to recapitulates the human tumor-immune-vascular niche and evaluate the therapeutic potential of targeting this critical signaling axis.

Results: We identified DCBLD2 as a dual regulator of angiogenesis and immunosuppression in lung cancer via WGCNA analysis, with pronounced expression in tumor cells (TCs) and clinical specimens. Genetic ablation of Dcbld2 in TCs significantly attenuated angiogenesis and potentiated immunotherapy response in murine lung cancer xenograft models. Single-cell/spatial profiling revealed SPP1high-TAMs preferentially surrounding DCBLD2+ tumors, induced by tumor-derived retinoic acid (RA). Specifically, RA stabilizes SPP1 mRNA in macrophages by triggering KAT2A-mediated acetylation of IGF2BP1, thereby blocking its proteasomal degradation. This post-translational modification reinforces IGF2BP1-dependent SPP1 transcript stabilization, fostering an immunosuppressive TME characterized by SPP1high-TAM accumulation and CD8+ T-cell exclusion. Therapeutically, pharmacological inhibition of RA signaling markedly reduced tumor progression and synergized with immune checkpoint blockade in both syngeneic murine models and humanized PDX systems, underscoring its translational potential as a combinatorial strategy to overcome immunotherapy resistance.

Conclusions: Targeting DCBLD2-RA signaling disrupts immunosuppressive vascular niches, providing a dual strategy to recondition the TME and restore immunotherapy efficacy in lung cancer.

OA14.03 Functional Characterization of Osimertinib-Induced Drug Tolerant Persisters in Lung Adenocarcinoma

K.A. Gorospe[1,2,3], E. Ortiz[1], N-A. Pham[3], R. Navab[3], M-S. Tsao[3], K.L. Thu[2]
[1]University of Toronto, Toronto/ON/CA ,[2]Keenan Research Centre for Biomedical Science, Toronto/ON/CA ,[3]Princess Margaret Cancer Centre, Toronto/ON/CA

Introduction: Resistance to epidermal growth factor receptor (EGFR)-targeted therapy limits survival in lung adenocarcinoma (LUAD) patients with activating EGFR mutations (EGFRmut). Resistance can stem from drug-tolerant persister cells (DTPs), a rare, slow-growing population of cells that survives tyrosine kinase inhibitor (TKI) treatment, which contributes to minimal residual disease and eventual tumor recurrence. Understanding DTP survival mechanisms in EGFRmut LUAD may uncover therapeutic vulnerabilities that could be targeted to enhance TKI efficacy, but these mechanisms remain poorly characterized. Using EGFRmut LUAD patient-derived xenograft (PDX) models, our lab previously profiled gene expression changes in DTP tumors induced by the first-generation TKI, erlotinib, compared to treatment naïve controls (Moghal et al., J Thoracic Oncol, 2023; 18: 499-515). We identified several genes that were upregulated in DTPs and significantly enriched for pathways associated with NFkB and STAT3 signaling. We hypothesize that inhibiting these signaling pathways in combination with the third-generation TKI, osimertinib (Osi), will abrogate DTP formation and circumvent resistance to Osi in EGFRmut LUAD. This project sought to determine whether inhibiting NFkB and STAT3 signaling via genetic perturbation of the RELA and STAT3 genes increases sensitivity to Osi in LUAD models.

Methods: CRISPR-mediated gene editing was used to engineer the EGFRmut LUAD cell lines PC9 and HCC4006 (both EGFR exon 19 deletion) with RELA and STAT3 LOF. Lentiviral plasmids containing single-guide RNA (sgRNAs) targeting RELA and STAT3, or AAVS1 as a negative control, were transduced into Cas9+ cells. Loss of protein expression was validated in clonally derived lines using immunoblotting. Cell lines were treated with 2 μM Osi for 3 days (d) to assess the effects of gene LOF on apoptosis measured by flow cytometry. The capacity for cells with RELA and STAT3 LOF to form DTPs was evaluated using clonogenic survival assays. Cells were treated for 12d with 2 μM Osi and surviving, drug-tolerant colonies were stained with sulforhodamine B and counted.

Results: To date, we confirmed that RELA was transcriptionally upregulated in PC9 and HCC4006 cells following short- and long-term Osi treatment. However, STAT3 mRNA was downregulated. RELA and STAT3 LOF potentiated apoptosis induced by acute Osi treatment, suggesting that STAT3- and RELA-driven mechanisms mediate response to Osi. Additionally, RELA and STAT3 LOF reduced the clonogenic survival of Osi-treated cells compared to control cells, further implicating these genes in regulating DTP survival.

Conclusions: Upregulation of RELA in PC9 and HCC4006 DTPs further implicates NFkB signaling as a potential DTP survival mechanism. This suggests that activation of NFkB is a generalizable mechanism enabling drug tolerance across cell line and PDX models of EGFRmut LUAD. The increased apoptotic response and reduced clonogenic potential observed upon combining Osi with STAT3 and RELA LOF highlight their promise as targets for abrogating DTP survival. These findings could inform novel interventions for preventing tumor relapse following osimertinib therapy in EGFRmut LUAD patients.

OA14.04 Genetic Inactivation of the Epigenetic Regulator ATF7IP: Functional Impact in Lung Adenocarcinomas

J.M. Morillas[1], O.A. Romero[1], E. Pros[1], M. Branco[2], M. Sanchez-Cespedes[1]
[1]Josep Carreras Leukemia Research Institute - IJC, Badalona/ES ,[2]Queen Mary University of London, London/G

Introduction: The genetic characterization of lung cancer (LC) has been of paramount importance to improve its diagnosis and treatment. Identification of oncogenes that are involved in LC development has allowed for the development of novel and effective therapeutic strategies, such as tyrosine kinase inhibitors. However, to this date, no therapeutic strategies are available based on the presence of inactivating mutations at tumor suppressor genes (TSGs). An earlier report from our group found epigenetic regulator ATF7IP to show a strong bias towards inactivating mutations in lung adenocarcinoma (LuAD) cohorts, making it a strong TSG candidate. ATF7IP's best known function is to promote the nuclear activity of epigenetic silencer SETDB1, which catalyzes the deposition of H3K9me3, an epigenetic mark that leads to gene silencing. Because ATF7IP's role in LuAD development remains unexplored, we aim to understand its loss' contribution to oncogenesis.

Methods: We selected a panel of ATF7IP-deficient LuAD cell lines and restored wild-type ATF7IP in them in a doxycycline-inducible manner. We measured global changes in ATF7IP, SETDB1 and H3K9me3 levels upon doxycycline induction using Western Blot, and immunofluorescence was used to evaluate ATF7IP's impact on SETDB1's subcellular localization. In order to study ATF7IP's impact in tumor growth, tumor spheroids were established using low-adherence 96-well plates. To understand ATF7IP's impact on transcription, we performed bulk mRNA-seq from induced and control cells. We also performed ChIP-seq of both SETDB1 and H3K9me3 to evaluate how ATF7IP affects SETDB1's binding to chromatin, as well as to assess its function.

Results: We show that restoring wild-type ATF7IP expression leads to an accumulation at the protein level- but not at the mRNA level- of SETDB1, concomitant with a global increase in global H3K9me3. We observe that ATF7IP-deficient LC cells show a mostly cytosolic location of SETDB1, which becomes intranuclear upon ATF7IP recovery, consistent with previous reports. Upon overexpression of wild-type ATF7IP, tumor spheroid growth was impaired in ATF7IP-deficient cells, unlike control cells. Re-expression of ATF7IP in deficient cells results in global transcriptional repression. Genes related to meiosis, extracellular matrix remodeling and neuronal development experience a strong downregulation. Notably, transcripts derived from endogenous retroviruses (ERVs), such as DHRS2, are also particularly repressed. ChIP-seq revealed that ATF7IP promotes SETDB1's binding to chromatin and the deposition of H3K9me3 in regions surrounding SETDB1 peaks. Downregulated genes are significantly close to SETDB1 peaks. Of note, SETDB1 binds to the 3' end of zinc finger proteins (ZFPs) found in clusters scattered throughout the genome, as well as to other clustered families of genes.

Conclusions: Our work offers evidence of ATF7IP's role as a TSG, and explores the consequences at the molecular and cellular levels of the loss of ATF7IP in LuAD cells. We provide an insight into the pathways that become deregulated in ATF7IP-deficient tumors and the epigenetic mechanisms that mediate these changes. This knowledge informs us of upstream and downstream pathways that ATF7IP-deficient cells may grow dependent on, and that we may potentially target pharmacologically, allowing us to selectively attack tumor cells.

Introduction: Lung cancer is the leading cause of cancer death worldwide in both men and women. It is a highly heterogeneous disease primarily driven by tobacco smoking. About 20% of lung cancers occur among never smokers. There are major differences between lung cancers in patients who have never smoked (LCINS) and who have smoked in patient ancestry, sex, tumor histology, and clinical features. For example, LCINS occur more frequently in Asians and females and are predominantly adenocarcinomas. EGFR mutations are enriched in LCINS, whereas KRAS and TP53 mutations are more common in tumors from smokers. Our understanding of the etiology of lung cancer in patients who have never smoked is still limited.

Methods: Here, we perform a comprehensive study in 1,209 whole-genome sequenced (WGS) lung cancers collected from 30 different locations across four continents through Sherlock-Lung Project from the National Cancer Institute (NCI) as well as published studies. Among these tumors, 1024 of them are adenocarcinomas and 864 are from patients who have never smoked. Two-thirds (811) of the patients are of European ancestry whereas one-third (359) are of East Asian ancestry. A small fraction of patients (39) had South American and African ancestries. This cohort represents the largest genomics cohort in lung cancer to date. In addition to WGS, other omics data are generated on Sherlock-Lung samples, including RNA-Seq and methylation arrays. Our study focuses on chromosomal instability which is of clinical importance in lung cancer because gene fusions caused by somatic structural variations (SVs), large-scale chromosomal rearrangements, are major oncogenic drivers of lung cancer. Somatic SVs are detected in tumor samples by comparing tumor genomes against germline genomes from blood or adjacent normal tissues from the same patients. We perform comprehensive analysis of somatic SVs in this diverse cohort to better understand the genomic landscape of lung cancer.

Results: In total, we detect 182,429 somatic SVs in 1209 tumor samples with an average of 151 SVs per sample. Complex SVs, such as chromothripsis and chromoplexy, are studied separately from simple SVs which are composed of deletions, tandem duplications, inversions and translocations. This is because complex SVs arise through one-time catastrophic events and are distinct from simple SVs which occur one by one and accumulate in the genome over time. In these catastrophic events, chromosomes are shattered into pieces, rejoin and form new chromosomes with many SVs formed. About two-thirds of the SVs in our cohort are part of complex events. We further derive SV-based mutational signatures, reflecting molecular mechanisms that can be mathematically decomposed. We deconvolute complex SV signatures based on SV breakpoint and copy number patterns and decompose simple SV signatures based on SV type and size using a non-negative matrix factorization approach. A total of 8 complex SV signatures and 8 simple SV signatures are discovered in our cohort which likely represent divergent molecular mechanisms. Among these, chromatin bridge signature, driven by dicentric chromosomes, is the most abundant complex SVs and median size deletion is the most common simple SVs. SVs are more abundant in tumors from patients who have smoked; however, they are more complex and play more important roles in tumorigenesis in tumors from patients who have never smoked. The SV breakpoints have distinct distributions across the genome depending on the signatures due to combined effects of mutagenesis and positive selection. Many established cancer-driving genes are recurrently rearranged by multiple SV signatures suggesting functional convergence of these genome instability mechanisms. We find that, in addition to smoking, EGFR mutations and KRAS mutations profoundly and independently shape the SV landscape. EGFR-mutant tumors have higher SV burden and more cancer-driving SVs. In contrast, KRAS mutations are associated with lower SV burden and less driver SVs. In a separate analysis using the same Sherlock-Lung samples and recently published in Nature (https://www.nature.com/articles/s41586-025-09219-0), we report that mutational signatures in tumors from patients who have never smoked are primarily driven by aging and other endogenous processes, and are positively associated with air pollution but not associated with secondhand smoking. Our study, in conjunction with multiple companion studies on this patient cohort, has deepened our understanding of genomic landscape and etiology of lung cancer.

OA15.01 Results of the Croatian National Lung Cancer Screening Program

M. Samaržija[1], K. Krpina[1], A. Aboud[1], M. Jakopović[1], M. Hrabak Paar[1], A. Marušić[2], V. Amerl Šakić[3], T. Benjak[4], R. Yip[5], D. Yankelevitz[5], C. Henschke[5]
[1]University hospital centre Zagreb, Zagreb/HR ,[2]University of Split, Split/HR ,[3]General Practitioner, Zagreb/HR ,[4]Croatian Institute of Public Health, Zagreb/HR ,[5]Icahn School of Medicine at Mount Sinai, New York/NY/USA

Introduction: Lung cancer is the leading cause of death from malignant diseases, both worldwide and in Croatia. With more than 3300 new diagnoses of lung cancer and more than 2800 lung cancer deaths in 2019, lung cancer remains one of the main public health problems in Croatia. Taking into consideration the aforementioned data, along with a high smoking prevalence among adults, high incidence to mortality ratio and large proportion of lung cancer in advance stages in Croatia, Ministry of health formed a multidisciplinary working group with the task of implementing a nation wide lung cancer screening program.

Methods: The Croatian National Lung Cancer Screening Program was implemented in Oct 2020 in accordance with published scientific data and recommendations from European Position Statement on Lung Cancer Screening, adopting modified I-ELCAP guidelines, using Low Dose CT scans (LDCT), artificial intelligence, volumetric analysis of lung nodules and is completely digitalized. This is the first national lung cancer screening program in the European Union and completely integrated into the existing healthcare system. The main difference when compared to other lung cancer screening programs is the placement of General Practitioners in the central role of enrolling the high-risk population. The results shown focus on cancer findings.

Results: From October 2020 - October 2024, 34 648 participants were screened, age range 50-75, persons who smoke or had quit smoking during the last 15 years, with at least 30 pack years smoking history. There were 45 341 LDCT scans performed, 34 648 baseline scans and 10 693 follow up scans; 54% male vs 46% female with an median age of 62. Among these 34 648 participants there were 2 027 (5.8%) who required referral to one of six Lung Nodule Clinics that were established as a part of the screening program, for further investigation. There were 669 cancers found; 615 lung cancer (92%) and 54 other sites (8%). Out of 615 lung cancers, 46.5% were diagnosed in early stage and had a surgical resection; 35.8% stage 1 and 10.7% stage 2; the remaining cases included 21.5% stage 3 and 29.5% stage 4 (staging for 2.5% in this moment is unknown). Additionally, within the cohort, there were 14 hamartomas found and 22 nonmalignant resections (TBC, granuloma ect.)

Conclusions: These initial results on a national level show an evident stage shift in lung cancer diagnosis, with an increase in early stage (stage 1 and 2). It is expected that the proportion of early stages will be higher as the program continues to run, which leads to improved survival rate and treatment outcomes. The final goal of the program is to decrease the mortality of lung cancer by 20% after 10 years of its implementation and to improved cure rate of lung cancer.

OA15.02 Preliminary Results of the Singapore Lung Cancer Screening Through Integrating CT With Other Biomarkers (SOLSTICE) Study

G.G.Y. Lai[1], G.S.K. Ooi[1], C.M.L. Chia[2], C.W. Too[3], S. Ganti[4], M. Huang[2], S.P.L. Saw[1], W.C. Tan[1], S.M. Haja Mohideen[3], W.P. Tham[3], W.S. Ong[1], L.Y. Ho[1], Z.Y. Ng[1], B.H. Ong[2], D. Anantham[3], D.S.W. Tan[1], D.W.T. Lim[1]
[1]National Cancer Centre Singapore, Singapore/SG ,[2]National Heart Centre Singapore, Singapore/SG ,[3]Singapore General Hospital, Singapore/SG ,[4]Sengkang General Hospital, Singapore/SG

Introduction: Lung cancer (LC) is one of the leading causes of cancer-related mortality in Singapore with approximately 60% of patients diagnosed with advanced, incurable disease. LC screening may potentially increase early detection and reduce mortality. While smoking is traditionally the key risk factor for LC development, family history is increasingly recognized as an association particularly amongst never smokers. With recommendations for screening by low-dose CT thorax (LDCT) limited to smokers in many countries including Singapore, we sought to conduct the ongoing SOLSTICE study (NCT05724264) to evaluate the feasibility of a LC screening programme in both smokers and at-risk non-smokers.

Methods: This single arm prospective screening trial is the first LC screening study in Singapore. Both smokers (S) and non-smokers (NS) with known family history of LC up to 2nd degree are eligible, and age range for inclusion is 50-80 years. All participants undergo a baseline LDCT reported based on Lung-RADS v1.1 (LR), which guides downstream management including interval of surveillance or intervention. A negative result (LR 1/2) is followed by 2 annual LDCT for S and 1 biennial LDCT for NS. All incidental findings are managed with multidisciplinary input via standardized pathways.

Results: 420 participants (62 S, 358 NS) underwent a baseline LDCT between 17 Feb 2023 and 12 Feb 2025. Their median age was 61 years (range, 50-78 years). 305 (85.2%) of NS had a 1st degree relative with lung cancer. At baseline, 5 were LR0 (1.2%), 165 (39.3%) were LR1, 236 (56.2%) were LR2, 7 (1.7%) were LR3, and 7 (1.7%) were LR4. 1 LR4 lesion was histologically proven as organizing pneumonia on biopsy. There were 8 diagnosed cancers for a LC detection rate of 1.9%, all of which were stage 1A lung adenocarcinomas (LUAD) in NS that underwent surgical resection. 7/8 (87.5%) had a 1st degree family history and 4/8 (50%) were female. 5/8 LC (62.5%) were LR2 on baseline LDCT, while the other 3/8 consisted of 1 LR3 (12.5%) and 2 LR4 (25%). Of the 6 LUAD with genomic profiling, 5 (83.3%) had EGFR mutation and 1 (16.7%) had ERBB2 mutation.

330 incidental findings were picked up in 232/420 (55.2%) participants, with 15/330 (4.5%) deemed potentially significant. Cardiac incidentals were most common (130, 39.4%), followed by liver (69, 20.9%) then thyroid (33, 10%). All 130 participants with incidental cardiac abnormalities had coronary calcifications, of which 1 required cardiac revascularization for ischemic heart disease. There was also 1 participant with an incidental diagnosis of Type AB thymoma, Modified Masaoka Stage IIB, who underwent surgical resection.

Conclusions: Preliminary results from SOLSTICE have demonstrated a LC detection rate of 1.9%, comparable to the Taiwanese TALENT study in NS, and NLST/ NELSON in S. Geographical diversity of LC molecular subtypes, as well as a preponderance for ground glass opacity-associated LC, will warrant a relook at the eligibility criteria for LC screening and the adoption of LR for management of screen-detected nodules in Asia. Standardized reporting of incidentals is also crucial for stratification and rationalization of downstream subspecialty referrals.

OA16.02 RAPID-RT: Using Rapid-Learning to Assess the Survival Impact of Limiting Dose to a New Cardiac Avoidance Area During Lung Cancer Radiotherapy

C. Faivre-Finn[1], C. Morgan[1], T. Marchant[2], K. Banfill[2], A. Walker[2], A. McWilliam[1], M. van Herk[1], N. Bayman[2], R. Holley[1], D. Woolf[2], C. Barker[2], J. King[2], C. Chan[2], L. Pemberton[2], J. Coote[2], H. Sheikh[2], D. Abdulwahid[2], C. Harris[2], J. Wood[2], G. Price[1]
[1]The University of Manchester, Manchester/GB ,[2]The Christie NHS Trust, Manchester/GB

Introduction: Evaluating radiotherapy changes in conventional trials is challenging due to a lack of equipoise, selection bias, and resource limitations. High-quality prospective real-world data and rapid-learning approaches offer a more inclusive, practical solution. Emerging evidence suggests that limiting radiation dose to a new Cardiac Avoidance Area (CAA)—comprising the right atrium, proximal coronary arteries, and aortic valve—may improve survival in lung cancer patients receiving curative-intent radiotherapy (doi:10.1016/j.jtocrr.2024.100742). The RAPID-RT study (ISRCTN17129364) is the first prospective study using rapid-learning and opt-out consent to evaluate the impact of CAA dose limitation on survival.

Methods: In April 2023 our institution became the first to implement CAA-based planning for all patients receiving non-SABR, curative radiotherapy for stage I-III lung cancer. Dmax to 1cc of the CAA is limited to 19.5Gy for 20 fractions (or equivalent) unless conflicting with target coverage. Patients treated with the CAA dose limit (cohort 2) are prospectively enrolled via an informed opt-out consent process and compared to those treated prior to its introduction (cohort 1). Routine clinical data is collected from the electronic patient record, including demographic, tumour, treatment, and survival data. Missing data will be addressed via Multiple Imputation. The primary endpoints are overall survival and survival at one year. Survival was modelled using a Bayesian parametric Weibull distribution adjusting for prognostic factors and using uninformative priors.

Results: Between 1/2021 - 2/2025, 922 and 786 patients were included in cohorts 1 and 2 (average missingness 6.7%). Cohorts were well balanced (figure1), except for volumetric arc therapy use increasing from 93.2% in cohort 2 vs 31.6% of cohort 1. The proportion of patients not achieving the CAA constraint reduced from 56.8% to 29.7%, with little impact on other organs-at-risk dose-volume histograms. Early results show that the rapid-learning method is highly inclusive as all patients received the new technique, with only 1 out of 786 patients choosing to opt out in cohort 2. Initial findings suggest a survival benefit in cohort 2 with a population average 12-month survival probability of 0.738 (0.673, 0.802) in cohort 2 compared to 0.682 (0.642, 0.744) in cohort 1. Updated data will be presented at WCLC 2025.

Conclusions: We demonstrate, for the first time, that rapid-learning using real-world data can quickly evaluate a change in radiotherapy practice. Initial results suggest improved survival with CAA dose limitation in a representative lung cancer population. Ongoing analyses will assess the impact on longer-term survival, toxicities, and explore alternative modelling approaches.

OA16.03 Sequencing of Radiotherapy and Immunotherapy Stratifies Pneumonitis Risk: A Propensity-Matched Multicenter Study

W. Wei[1], Y. Ruan[2], Y. Zhang[2], z. Rong[2], Z. Dong[2]
[1]XiangYang Central Hospital, Affiliated Hospital of Hubei University of Arts and Science, XiangYang/CN ,[2]Nanfang Hospital, Southern Medical University, Guangzhou/CN

Introduction: The combination of immune checkpoint inhibitors (ICIs) with radiotherapy (RT) improves survival in advanced lung cancer. Evidence for the impact of sequencing radiotherapy and immunotherapy on treatment-related penumonitis (TRP) risk stratification is limited.

Methods: In a multicenter retrospective cohort of 1376 lung cancer patients from 2021 to 2023, 262 receiving thoracic radiotherapy combined with ICIs selected after rigorous screening. Patients were categorized into two groups based on treatment sequence(immunotherapy followed by sequential radiotherapy/ICIs+RT vs radiotherapy followed by sequential immunotherapy/RT+ICIs). A balanced cohort was constructed using 1:2 propensity score matching (PSM) with covariates including V5, V20, Dmean, and ICI type. Univariate and multivariate logistic regression models analyzed interaction between treatment sequence and treatment-related parameters, and helped select variables to establish a nomogram for TRP.

Results: Prior to matching, the ICIs+RT group (n=187) exhibited a significantly higher incidence of TRP than the RT+ICIs group (61.0% vs. 49.3%, n=75). Baseline imbalances were observed in dosimetric parameters (PTV, V5, V20, Dmean), ICIs type/cycles, and CCRT utilization (all P<0.05). Following 1:2 PSM, covariates between the ICIs+RT (n=126) and RT+ICIs cohorts (n=67) were balanced (P>0.05). Multivariate analysis identified treatment sequence as an independent predictor of TRP risk, with adjusted odds ratios (ORs) of 0.434 (95% CI: 0.217-0.868; P=0.018) for grade ≥1 TRP and 0.433 (95% CI: 0.213-0.880; P=0.021) for grade ≥2 TRP, suggesting improved safety with RT-ICIs sequencing. Additionally, ICIs cycles and Dmean were integrated with treatment order to develop a nomogram for grade ≥2 TRP prediction. The model demonstrated robust performance, supported by an AUC of 0.726 (95% CI: 0.654-0.789), well-fitted calibration curves, and favorable clinical utility on decision curve analysis.

Conclusions: This study applies propensity score matching-adjusted analysis to reveal graded impacts of treatment sequence on TRP severity, providing pivotal evidence to optimize combined therapy safety and personalize treatment strategies in lung cancer.

OA16.04 Prognostic Value of Residual Viable Tumor in Lymph Nodes of Non-Small Cell Lung Cancer After Neoadjuvant Chemoimmunotherapy

T. Han, H. Zhao, S. Cheng, K. Chen, F. Yang, H. Li
Peking University People's Hospital, Beijing/CN

Introduction: Current major pathologic response (MPR) criteria for neoadjuvant chemoimmunotherapy in non-small cell lung cancer (NSCLC) primarily focus on primary tumor (PT) response, with lymph node response inconsistently incorporated. The prognostic significance of pathologic regression in metastatic lymph nodes (mLNs) remains unclear. This study aimed to assess its impact on recurrence-free survival (RFS) and establish an effective prognostic stratification system.

Methods: We identified 87 patients with resectable NSCLC and pathologically confirmed mLNs who underwent neoadjuvant chemoimmunotherapy and surgery between 2021 and 2024. The percentage of residual viable tumor (%RVT) in mLNs was quantified (range 0-100%) based on pan-tumor immune-related pathologic response criteria. The mean %RVT in mLNs and positive lymph node ratio (LNR) of each patient were calculated, and their optimal cutoffs for RFS were determined using maximally selected rank statistics. Kaplan-Meier analysis and Cox regression was performed to evaluate prognostic significance.

Results: The median follow-up time was 12.8 months (95%CI: 10.1-16.8), during which 25 recurrences were observed. The median %RVT in mLNs was 24% (IQR 0-60%). A %RVT cutoff of 20% in mLNs was significantly associated with RFS (HR = 0.27, 95%CI: 0.11-0.68, p = 0.003). Multivariable Cox regression confirmed %RVT > 20% as an independent risk factor for RFS (HR = 3.18, 95%CI: 1.20-8.38, p = 0.020). Using optimal cutoffs for LNR and %RVT (both at 20%), we developed a lymph node tumor burden (LNTB) score: score 1 for %RVT≤20%, score 2 for %RVT>20% and LNR ≤20%, and score 3 for %RVT>20% and LNR>20%. A novel prognostic stratification model integrating LNTB score and PT-MPR status effectively distinguished patients into three risk groups: low (PT-MPR+LNTB 1), intermediate (PT-non-MPR+ LNTB 1& PT-MPR/non-MPR+LNTB 2), and high (PT-MPR/non-MPR+LNTB 3). RFS differed significantly across them (log-rank p < 0.001), with 2-year RFS rates of 91.6%, 59.0%, and 38.7%, respectively. The low-risk group demonstrated significantly improved RFS than intermediate-risk group (HR = 0.20, 95%CI: 0.05-0.91, p = 0.037), and the intermediate-risk group had better outcomes than high-risk group (HR = 0.40, 95%CI: 0.18-0.92, p = 0.030). The combined model demonstrated superior predictive accuracy, with an AUC of 0.78 (95%CI: 0.65-0.90), outperforming other models including ypTNM staging.

Conclusions: The pathologic response in lymph nodes independently predicts recurrence risk in NSCLC patients following neoadjuvant chemoimmunotherapy. Compared to conventional ypTNM staging, the novel stratification system-integrating lymph node tumor burden and primary tumor response-provides more accurate prognostic information and may offer valuable guidance for postoperative management.

OA17.01 Stigma and Psychological Distress in Patients with Lung Cancer: A Possible Role of EMDR (Eye Movement Desensitization and Reprocessing) Therapy

A. Catino[1], D. Bafunno[1], G. D'Alonzo[1], E. Faretta[2], A. De Leo[1], V. Lamorgese[1], E.S. Montagna[1], F. Pesola[1], M. Montrone[1], V. Longo[1], M. Moro[1], M. Gesualdo[1], P. Pizzutilo[1], I. Marech[1], S. Donvito[1], P. Petrillo[1], D. De Pinto[1], D. Galetta[1]
[1]IRCCS Istituto Tumori "Giovanni Paolo II", BARI/IT ,[2]Centro di Ricerca e Psicoterapia Integrata EMDR, Milano/IT

Introduction: Psychological distress is common in patients with lung cancer, and has a severe negative impact on quality of life. Anxiety and depression are the most frequently reported symptoms . In some cases cancer may cause stigma , often linked to the belief that the patient's behavior (e. g . smoking) caused the disease , and may represent a traumatic event leading to Post Traumatic Stress Disorder (PTSD). Eye Movement Desensitization and Reprocessing (EMDR) therapy is an evidence-based treatment for PTSD, and has shown promising results in reducing anxiety and depression.

Methods: The primary aim of this study was to assess distress levels and the presence of health-related stigma in patients with lung cancer. A secondary aim was to evaluate emotional distress before and after EMDR therapy.

Participants completed questionnaires collecting data on age, sex, education, PTSD symptoms by IES-R (Impact Event Symptoms -Revised), HADS (Hospital Anxiety and Depression Scale) and health-related stigma by CLCSS (Cataldo Lung Cancer Stigma Scale).

Results: From March 2024 to March 2025, 19 participants with lung cancer were enrolled. Mean age was 63 years (SD = 8.3, range = 36-74), 53% were female, and 54% were current or former smokers.

The mean IES-R score was 47.8 (SD ± 23.2). While 74% scored below the PTSD threshold (<21), 26% met criteria for mild PTSD (>21). 63% (N=12) were above the HADS global distress cut-off (≥16). 68.4% (N=13) exceeded the HADS-Anxiety cut-off (≥8), and 52.6% (N=10) exceeded the HADS-Depression cut-off.

Higher stigma levels were significantly associated with more depression ($r = .49$; $p < .05$), PTSD intrusion symptoms ($r = .48$; $p < .05$), and hyperarousal ($r = .47$; $p < .05$). No significant differences were found between persons who currently smoke or who don't smoke .

Pre- and post-EMDR assessments showed significant reductions in PTSD symptoms (IES-R, all scales $p < .05$), anxiety, and depression (HADS, $p < .05$).

Conclusions: Stigma can worsen psychological well-being in patients with lung cancer . Routine assessment of stigma may help identify those at higher risk of distress. Trauma-focused treatments like EMDR may represent a valuable addition in the oncological care setting.

OA17.03 The Patient Voice on Required Research Biopsies: Results of a Survey Study Exploring the Perspective of Patients With Lung Cancer

F. Abodunrin[1], M. Kaye[2], A. Esposito[1], J. Feldman[3], I. Elkins (In Memoriam)[3], U.B. Roy[4], A. Wozniak[5], N. Choudhury[1], E.E. Vokes[1], M.C. Garassino[1], C.M. Bestvina[1]

Introduction: In the last 20 years, biopsies in patients with lung cancer have led to major discoveries and advances. However, mandatory, research-only biopsies in clinical trials are a controversial and timely topic given the recent FDA's draft guidance. Access to new and innovative therapies through clinical trials can be contingent upon a patient's willingness to undergo CT-guided or bronchoscopic biopsies, which carry risk of pneumothorax and hospitalization. For this reason, understanding the patient perspective is more important than ever. These are the first results from a patient-centered survey exploring the perspectives of patients with lung cancer on the role and impact of research biopsies.

Methods: This survey study was conducted from October 2024 to January 2025 following approval by the University of Chicago Institutional Review Board. The study was designed in collaboration with patient advocates with lung cancer and the University of Chicago Booth School of Business. Patients were recruited by LUNGevity and the Lung Cancer Research Foundation. A 40-item, self-administered online survey assessed demographics, stage, number of prior treatments, and academic versus non-academic treatment. Also assessed were prior biopsies, clinical trial participation, and six items evaluating willingness to consent to biopsies in clinical trials solely for research purposes. These six items were summed to provide a general acceptance of research-only biopsies. Results of a two-step hierarchical regression predicted the influence of treatment (Step 1) and demographic factors (Step 2) on acceptance of research-only biopsies. Statistical analysis was conducted using SPSS v29. All the analyses were blinded to the investigators and performed by an independent team.

Results: Of the 118 responses, participants were predominantly under 60 (51%), female (60%), non-Hispanic (83%), stage IV diagnosis (41%), and had received 1-2 prior treatments (62%). Over 75% of participants indicated a willingness to undergo research-only biopsies, and indicated it was definitely or probably OK to obtain those biopsies (Range1(definitely no)-5(definitely yes); M = 3.883, SD = 0.937). Participants were also open to asking patients to have a lung biopsy for research, even knowing that there is a chance of lung puncture (Range 1 (never ok)-5 (always ok); M = 4.551; SD = 0.843). Receiving treatment at an academic facility predicted a lower level of acceptance (β = -0.234, $p < .01$) and having received a higher number of prior treatments for lung cancer predicted higher acceptance of biopsies (β = 0.238, $p < .01$; adjusted $R2 = .089$, $p = .003$). Gender, age, education, and race predicted nearly 27% of the variance in acceptance (adjusted $R2 = .269$, $p < .001$) with higher acceptance reported by male (β = -0.241, $p < .001$) and younger (β = -0.293, $p < .001$) participants.

Conclusions: This is the first survey that explored patient's perspective in an independent way. Overall, patients with lung cancer express a willingness to undergo research-only biopsies, recognizing their potential to drive scientific progress. Their perspectives are critical and must be central to ongoing discussions surrounding FDA guidance on tissue biopsies in clinical trials.

OA17.04 Financial Toxicity in Patients Who Received Targeted Therapy for Lung Cancers

C. Burley1, M.Z. Guo2, Y. Wang1, C. Eaton1, S. Olson1, M.L. Hsu3, J. Feliciano2

[1]Johns Hopkins Bayview Medical Center, Baltimore/MD/USA ,[2]Johns Hopkins Hospital, Baltimore/MD/USA ,[3]Case Western Reserve University, Cleveland/OH/USA

Introduction: Financial toxicity (FT) is an increasingly recognized effect of cancer therapy and is associated with worsened quality of life, compliance, and possibly, mortality. Oral targeted therapy (OTT) has improved survival in lung cancer but little is known about the FT experienced by lung cancer survivors (LCS) receiving OTT. We evaluated clinical and sociodemographic factors in LCS receiving OTT, and whether receiving OTT was associated with greater FT.

Methods: LCS (defined as alive ≥1 year from diagnosis) treated at Johns Hopkins between 2020-2024 completed the COmprehensive Score for Financial Toxicity (COST), which is a validated, patient-reported outcome measure to assess subjective FT. Answers are rated on a 5-point Likert scale with lower scores representing higher financial needs. Demographic and clinical information was collected by chart review and survey response. The Wilcoxon rank sum test or Kruskal-Wallis test were used to assess univariate associations between patient demographic, clinical characteristics, and COST score.

Results: Of 326 patients enrolled, 307 had complete survey data (>80% items complete) and were included for analysis (Table 1). Respondents who ever received OTT (n=111) were younger (51% <65), less likely to have ever smoked (61% never smoker), more likely to be privately insured (79%), endorse household income >$75,000 (67%), and educational attainment of college degree or greater (47%) compared to respondents who never received OTT. The majority of OTT patients had adenocarcinoma (96%) and were Stage IV (69%) at time of diagnosis. Financial needs were reported by all patients regardless of OTT treatment (45% vs 33%, ever vs never OTT). Patients who received OTT had comparable FT scores with patients who never received OTT (ever vs never OTT, COST = 26, 28, respectively). Similarly, when limited to patients who were receiving palliative intent therapy, OTT treatment was not associated with a significant difference in COST score (95% CI -1.03, 3.39, p=0.295). Among patients who ever received OTT, age (<65 vs > 65, COST = 25, 28, respectively; p=0.009) and patient-identified race (Caucasian, African-American, Asian, Other, COST= 26.5, 27.5, 23, 37.4, respectively, p=0.034) were significantly associated with lower FT scores.

Conclusions: OTT treatment was not associated with differences in FT in a large group of LCS, even after excluding patients on curative intent therapy. Among patients receiving OTTs, younger age and race were associated with significant differences in FT. Targeted inventions to address these unmet needs and financial toxicity in LCS, regardless of therapy type, are crucial.

Introduction: Over 2 million people are diagnosed with lung cancer globally each year; that number is expected to almost double by 2050. The majority (80%) of cases are thought to be due to exposure to modifiable risk factors. Currently, 70% of people are diagnosed in advanced stages, limiting potentially curative treatment options. Policymakers are uniquely positioned to address these challenges. Therefore, this research aims to identify challenges in lung cancer risk reduction, early detection, treatment and survivorship, and highlights opportunities to enact policy change.

Methods: A comprehensive situational analysis of global lung cancer policy challenges was conducted across four themes: risk reduction, early detection, treatment and survivorship. Best-practice strategies and initiatives were also identified. The analysis was completed through a structured review of peer-reviewed and grey literature from 2018-2025, expert interviews and an online survey. Nine in-depth interviews were conducted with healthcare professionals and patient advocates in Australia, Canada, Colombia, Croatia, Hong Kong, Malaysia, the United Kingdom and the United States; 12 more interviews were planned at time of writing. Additionally, an online survey was completed by 25 International Association for the Study of Lung Cancer (IASLC) Committee members.

Results: Opportunities for policy action were identified across the four themes, and corresponding policy recommendations will be developed. While tobacco use remains a key risk factor for lung cancer, implementation of the World Health Organization's (WHO's) Framework Convention for Tobacco Control (FCTC) varies considerably. However, countries that have adhered to the FCTC, particularly those with increased tobacco taxation, have seen greater cessation rates. Other risk factors, including outdoor and household air pollution, occupational exposures (coal dust, silica dust, asbestos, diesel exhaust fumes) and radon exposure, are of growing concern.Lung cancer is being detected in advanced stages in many countries, precluding potentially curative therapeutic options. National screening programs are important for earlier detection, but equitable access remains a challenge and implementation is limited. Other early detection strategies (including awareness campaigns and rapid referral pathways) present further opportunities to expedite earlier detection, particularly in countries where screening is not feasible, and where rates of lung cancer in non-smoking populations are high. Access to care (including palliative care) is impeded by sociocultural and geographical barriers, and limited reimbursement of treatments. People can become lost in a complex system, with specialists spread across different health settings. Telehealth and patient navigators may ameliorate some of these challenges and facilitate more equitable care. Many countries do not have survivorship models incorporated into care pathways, and access to supportive care varies. Increased access to survivorship services (including rehabilitation and social support) would promote person-centered care.

Conclusions: The report - the first from the IASLC Global Policy and Partnerships Committee - identifies opportunities for policymakers to enact changes to promote equitable, person-centered lung cancer care that enhances survival and quality of life. These changes would lead to more efficient healthcare delivery, allowing for more proactive and preventive care, aligned with the United Nations' Sustainable Development Goals 3a and 3.4.

Introduction: Lung cancer is the leading cause of cancer-related mortality in the Americas, driven by an aging population, increasing exposures (pollution), social inequalities, and poor access to healthcare services. Despite advancements in risk reduction and early detection, significant disparities persist across countries, particularly those with limited resources. This study assessed lung cancer incidence and mortality rates for 2022 and projected trends up to 2050. It employs stratification by sex, age, and the Human Development Index (HDI) to emphasize the increasing regional and socioeconomic disparities regarding lung cancer.

Methods: Lung cancer incidence and mortality estimates for 2022, along with projections for 2050, were retrieved from GLOBOCAN 2022 database, the latest available. Age-standardized incidence and mortality rates (ASIR and ASMR, respectively) per 100,000 person-years were used for regional comparisons. Population data were obtained from the World Bank. Countries were categorized by HDI level (low, medium, high, very high), and analyses were stratified by sex and age group. Mann-Whitney U and Kruskal-Wallis tests were used for between-group comparisons, with Dunn's post hoc test for pairwise analysis. Median values were reported, with significance set at $p < 0.05$.

Results: Data from 34 countries in the Americas representing over 1 billion people (50.4% female) were analyzed. In 2022, the median ASIR and ASMR were 25.87 and 21.87 per 100,000, respectively. Lung cancer rates were significantly higher in males (ASIR: 14.23; ASMR: 11.99) than in females (ASIR: 6.32; ASMR: 5.08; $p < 0.001$). Uruguay reported the highest male lung cancer burden (ASIR: 46.56; ASMR: 41.76), whereas Guatemala had the lowest (ASIR: 4.50; ASMR: 4.23). Among female individuals, the United States had the highest ASIR (30.40), and Canada the highest ASMR (19.13). Guyana had the lowest female rates (ASIR and ASMR: 2.39). By 2050, lung cancer incidence and mortality are projected to increase at higher rates in female vs male individuals, by 87.9% and 89.4% vs 97.1% and 98.8%, respectively. Countries with low/medium HDI are expected to experience the most significant increases in incidence (118.9%) and mortality (120.0%) compared to high/very high HDI countries (87.5% and 89.2%, respectively). From the countries analyzed, nineteen (high/very high HDI: 14; low/medium HDI: 2; no HDI data available: 2) will see the greatest increase in female burden, when compared to male, highlighting an emerging gender and equity gap in lung cancer.

Conclusions: The lung cancer burden in the Americas is projected to rise substantially by 2050, with higher increases among women for the first time in history. Higher incidence increase was also seen in low/medium HDI countries. These findings highlight the urgent need for regionally tailored risk reduction strategies, enhanced access to screening and early diagnosis, and both regional and global collaboration to address the growing burden of lung cancer across the Americas.

OA18.03 Cost Effectiveness of Australian Lung Cancer Screening Eligibility Criteria: A Comparison Study

C. Kumarasamy, K. Betts, R. Norman, F. Brims
Curtin University, Perth/AU

Introduction: The Australian National Lung Cancer Screening Program (NLCSP) will commence in 2025. Screen eligibility for NLCSP uses smoking and tobacco exposure recommendations from the Medical Services Advisory Committee (MSAC). The MSAC criteria is stricter than similar criteria (USPSTF2021) used in the USA. Canadian provinces assess eligibility using the PLCOm2012 risk model, UK uses a combination of the PLCOm2012 and LLPv2 risk models. This study aimed to compare the cost effectiveness of the MSAC criteria against other eligibility criteria, using a microsimulation model estimating the benefit (life-years gained) of each criterion in a simulated Australian population.

Methods: The model simulated individual level outcomes based on initial parameters of age, sex and smoking status using Monte Carlo methods. The model was designed with 5 primary states, which included a baseline "healthy" state, and 4 disease states, each corresponding to the stages of LC diagnosis (Stage I - IV). There two additional terminal states: "lung-cancer mortality" and "other-cause mortality". Transition between these states were determined based on age, sex and stage specific LC incidence rates and mortality rates derived from data published by the Australian Institute of Health and Welfare (AIHW). Risk of lung cancer incidence and mortality due to tobacco smoking was adjusted using the Australian 45 and Up Study data.The final outcomes for each individual were: no disease, LC death, or death due to other causes. If death occurred due to LC, then the model also provided the number of years the individual spent in disease state, as well as the LC stage at which the individual was diagnosed.

Results: The model reported the potential life-years gained by screening under each eligibility criteria for a simulated population of 10,000 individuals, across 400 iterations of lifetime screening. Cost Effectiveness Acceptability Curves comparing each eligibility criteria (as an intervention versus a no-screening scenario) demonstrated that MSAC criteria was least likely to be cost effective at any given willingness-to-pay threshold for the health system (including screening and treatment costs: figure 1). One-way sensitivity analysis varying the CT costs, stage 4 treatment costs, incidence and other cause mortality rates, consistently highlighted MSAC as the least likely to be cost effective amongst all evaluated LC eligibility criteria.

Conclusions: Compared to other selection criteria, the Australian MSAC criteria is least likely to be cost-effective from a health system perspective. Refinement of selection criteria for the Australian NLCSP will likely be required after commencement in 2025.

Figure 1. Cost Effectiveness Acceptability (CEAC) curve comparing the assessed lung cancer eligibility criteria against no lung cancer screening

OA18.04 Sociodemographic and Healthcare Factors Associated With Enrollment in a Clinical Trial Integrating Tobacco Cessation and Lung Cancer Screening

E.J. Flores[1], C. Marotta[1], Y. Chang[1], B. Porneala[1], J. Avila[2], T. Liu[1], A.J. Wint[1], R.C. Carlos[3], J.M. Neil[4], L. Karout[1], I. Gonzalez[1], S.E. Howard[1], D.E. Levy[1], J.S. Haas[1], N.A. Rigotti[1], E. Park[1]
[1]Massachusetts General Hospital, Boston/MA/USA ,[2]University of Massachusetts Boston, Boston/MA/USA ,[3]Columbia University-New York Presbyterian Hospital, New York/NY/USA ,[4]University of Oklahoma Health Sciences Center, Oklahoma/OK/USA

Introduction: The factors influencing enrollment in a tobacco-cessation clinical trial (Screen ASSIST) among patients undergoing lung cancer screening (LCS) remain poorly understood. This study aims to assess the association of sociodemographic and healthcare factors with enrollment in the Screen ASSIST trial among individuals undergoing LCS.

Methods: This retrospective study used Screen ASSIST data, a Phase 4 randomized clinical trial that integrated tobacco cessation services and social support services among patients who currently smoke and were and scheduled for LCS across 11 sites within a large academic health system from April 2019-July 2023. Eligible participants included current smoking patients scheduled for LCS. Recruitment occurred at three points: (1) After LCS was ordered, (2) when performing LCS (RP2), and (3) after LCS results were available (RP3). Enrolled participants were randomly assigned in equal portions to one of eight study arms, following a 3-factor, fully crossed factorial design.Sociodemographics (age, gender, race, ethnicity, language, insurance, zip-code, and education) and healthcare-related factors (primary care physician visits over the past year, and Charlson comorbidity index) were extracted from electronic medical record. Neighborhood-level socioeconomic disadvantage was assessed using the Area deprivation index (ADI), based on participants' residential zip-code. Data were summarized using means with SD (continuous variables) and frequencies (categorical variables). Logistic regression assessed factors associated with enrollment, including variables of a priori importance (e.g. Charlson index, ADI) and significant factors identified in the univariate analysis ($p<0.05$). The primary outcome was enrollment in the clinical trial among individuals who met Screen ASSIST eligibility criteria.

Results: Among 4,090 eligible individuals, 642 (15.7%) were enrolled and randomized. Eligible individuals had a mean age of 63.0 (SD 6.5) and were predominantly White (80.1%), Non-Hispanic (83.7%), had English as preferred language (96.9%), and had high school degree or greater (77.1%). Groups did not differ by ADI or Charlson comorbidity scores. Univariate analyses showed higher enrollment among females ($p=0.019$), non-Hispanic Blacks ($p=0.002$), college graduates ($p<0.001$) and those without PCP visits in the previous year ($p=0.005$). Unenrolled individuals had a higher number of prior PCP visits (5.2, SD 6.9 visits) compared to enrolled individuals (4.7, SD 5.8 visits; $p=0.022$). Logistic regression analyses showed that factors associated with enrollment included: age 70 years or older (adjusted odds ratio [aOR]:1.29, 95% CI: 1.00 - 1.66); female gender (aOR: 1.26 95% CI: 1.06-1.50); self-reported non-Hispanic Black race (aOR: 1.87 95% CI: 1.37-2.54); college graduates education level (aOR: 1.47 95% CI: 1.03-2.12); and those with 0 PCP visits over the past year (aOR: 1.43 95% CI: 1.16-1.76).

Conclusions: Several sociodemographic and healthcare-related factors previously associated with lower clinical trial participation were, in this study, associated with a higher likelihood of enrollment in our tobacco cessation clinical trial integrated into LCS. These findings underscore a valuable opportunity to improve diversity in clinical trial participation and bridge existing disparities in lung cancer outcomes, cardiovascular disease and other smoking related diseases.

Introduction: Phase 2 NADIM II trial demonstrated that patients with resectable stage IIIA/IIIB NSCLC who received nivolumab in combination with platinum-based chemotherapy, achieved higher rates of pathological complete response and survival than those receiving chemotherapy alone. We analyze here perioperative outcomes and oncological quality of surgical procedures.

Methods: Variables related to surgical procedure were prospectively collected according to the study design. Additional data for the current analysis (surgical approach, operative time, hospital stay, 30 and 90-days mortality and surgical complications), were subsequently obtained from the surgeons participating in the trial. Complications were scored according to Clavien-Dindo Classification. Comprehensive Complication Index (CCI) was also used. Fulfillment of IASLC complete resection criteria was also evaluated.

Results: From the 86 randomized patients, 53 from the experimental group (93%) and 20 from the control arm (69%) finally underwent surgery as planned. No differences were found between both groups regarding comorbidities and basal lung function tests. Evolution of FEV1 and DLCO did not differ regardless type of neoadjuvance. Most tumors were in the upper lobes (64.4%) and in the right lung (72.8%). Mean time between the end of the induction treatment and surgery was 27.6 days. Lobectomy was performed in 79.4% of cases, whereas there were seven pneumonectomies (9.6%). Surgery was performed through a minimally invasive approach in 27% of cases. There were no differences in the type of resection and duration of surgical procedure. Postoperative complications appeared in 42.5% of patients, without differences between both groups. Persistent air leak (>5 days) was the most common (11 cases). Cardiac arrhythmia and pneumonia were recorded in 3 and 4 patients, respectively. CCI at discharge was 10.2 for control group and 7.8 for experimental arm (p=0.57). Median chest tube removal time (3 days) and hospital staying (4 days) non-significantly tended to be shorter in the experimental group. No re-operations were necessary. Four patients were readmitted after discharge (5.5%) and one patient undergoing right pneumonectomy died 13 days after surgery (30 and 90-days mortality 1.4%). Despite all the patients underwent R0 resection, 31 procedures (42.8%) did not fulfill IASLC criteria for complete resection. Figure shows reasons for non-compliance with them.

Conclusions: Induction treatment with the combination of platinum-based chemotherapy and nivolumab was safe and did not increase postoperative complications among patients included in NADIM II trial. Rates of R0 and uncertain resection were 100% and 42.8%, respectively. (NADIM II ClinicalTrials.gov number, NCT03838159; EudraCT number, 2018-004515-45.)

Introduction: Lung cancer remains the leading cause of cancer-related mortality worldwide. In locally advanced stages, the advent of perioperative chemoimmunotherapy has significantly improved survival outcomes. However, treatment responses remain highly variable, underscoring the need for reliable biomarkers to predict therapeutic efficacy. Metabolomics (the comprehensive analysis of small-molecule metabolites) has emerged as a powerful tool to identify metabolic alterations associated with cancer and immune modulation. Increasing evidence suggests that metabolic reprogramming plays a critical role in cancer development and may influence the response to immunotherapy. The NADIM II is an open-label, randomized, two-arm, phase II, multi-center trial designed to evaluate the efficacy of perioperative chemoimmunotherapy in patients with resectable stage IIIA-IIIB non-small cell lung cancer (NSCLC). Here, we present preliminary findings from a metabolomic analysis of plasma samples from study participants

Methods: In the NADIM II trial, patients with resectable stage IIIA/B NSCLC were randomized to receive neoadjuvant nivolumab plus platinum-based chemotherapy (experimental arm) or chemotherapy alone (control arm), followed by surgical resection. Patients in the experimental arm who achieved an R0 resection received adjuvant nivolumab for six months. Of the 86 patients randomized (57 in the experimental arm and 29 in the control arm), 81 plasma samples were available for metabolomic analysis (54 from the experimental arm and 27 from the control arm). Metabolomic profiling was conducted using liquid chromatography coupled with triple quadrupole mass spectrometry (LC-QqQ-MS/MS) in hydrophilic interaction liquid chromatography (HILIC) mode, targeting 190 polar metabolites. Compounds ionizing in positive mode were normalized using isotopically labeled internal standards. Statistical analysis was performed using RStudio to identify metabolites associated with survival outcomes.

Results: Among the 190 polar metabolites analyzed, histamine and 4-acetamidobutyric acid were significantly associated with improved survival in patients treated with neoadjuvant nivolumab plus chemotherapy ($P < 0.05$). This association was not observed in the control arm, where these metabolites did not correlate with survival outcomes. Conversely, orotic acid, 1-methylnicotinamide, and trigonelline emerged as independent negative predictive factors for response to perioperative chemoimmunotherapy, with significantly higher levels observed in patients with poorer survival outcomes ($P < 0.05$). Again, this pattern was not seen in the control arm. Notably, patients with histamine levels above the median were significantly more likely to achieve a pathological complete response ($P < 0.001$, Bonferroni-adjusted), and all of these patients were alive at the data cutoff (PlogRank = 0.002). In the same way, elevated histamine plasma levels were associated with significantly improved disease-free survival compared to patients with levels below the median (HR: 0.28; 95% CI: 0.092-0.83). No significant association between histamine levels and survival outcomes was observed in the control arm.

Conclusions: Plasma histamine levels are associated with pathological complete response and improved survival outcomes in patients with resectable NSCLC treated with perioperative chemoimmunotherapy.

MA01.04 Neoadjuvant PD-(L)1 Blockade in Combination With Chemotherapy for Borderline Resectable and Unresectable Stage III Non-Small Cell Lung Cancerl

B. Ricciuti[1], F. Fusco[2], A. Cooper[3], E. Garbo[1], F. Pecci[1], M. Aldea[1], X. Wang[1], M.M. Penalva[3], M. Ginsberg[3], L. Sholl[4], M. Nishino[4], A. Di Federico[1], N. Shaverdian[3], M. [1]Dana-Farber Cancer Institute, Boston/MA/USA ,[2]IRCCS Regina Elena National Cancer Institute, Rome/IT ,[3]Memorial Sloan Kettering Cancer Center, New York/NY/USA ,[4]Brigham and Women's Hospital, Boston/MA/USA ,[5]Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome/IT ,[6]Dana Farber Cancer Institute, Boston/MA/USA ,[7]Memorial Sloan Kettering Cancer Center, Boston/MA/USA

Introduction: Patients with borderline resectable or unresectable stage III non-small cell lung cancer (NSCLC) characterized by T4 and/or N2-N3 involvement face significant therapeutic challenges and generally poor outcomes. While concurrent chemoradiation has long been the standard of care, emerging evidence supports the potential of neoadjuvant chemo-immunotherapy to improve both surgical resectability and pathological response rates. However, data specific to this high-risk population remain limited as most of these patients have been excluded from clinical trials.

Methods: We conducted a multicenter cohort study of 112 patients with stage III NSCLC and T4 and/or N2-N3. All patients received neoadjuvant PD-1 blockade in combination with platinum-based chemotherapy. Pathological outcomes, including pathological complete response (pCR) and major pathological response (MPR), surgical resectability rates, and event-free survival (EFS) were assessed. Correlations between molecular features and treatment response were also explored.

Results: Of the 112 patients with borderline resectable and unresectable stage III NSCLC included, 75% proceeded to surgical resection following neoadjuvant treatment. Among resected patients, the pCR rate was 29.0%, and the MPR rate was 42.2% (Figure 1A). Patients with single versus multi-station N2 or N3 disease demonstrated comparable pathological response rates (P=0.6). The median EFS for resected patients was 52.6 months (95% CI: 27.8-not reached), and patients achieving pCR experienced significantly improved EFS (not reached vs. 27.8 months; P< 0.01). Patients who underwent surgery after neoadjuvant chemo-immunotherapy had significantly improved EFS and OS compared to those who were converted to definitive chemoradiotherapy (EFS HR: 0.31; P<0.01; OS HR: 0.33, P=0.01).

The pCR rate was highest (44.4%) among patients with both high PD-L1 expression (≥50%) and high TMB (≥50th percentile), compared to 33.3% in high PD-L1/low TMB, 14.3% in low PD-L1/high TMB, and 0% in low PD-L1/low TMB groups (P=0.03) (Figure 1B). Co-mutations in KRAS/STK11 or KRAS/KEAP1 were negatively associated with achieving pCR (pCR rate 0%, P<0.01 and P=0.05, respectively; Figure 1C). Clinical and genomic correlates of pCR and MPR are summarized in Figure 1D.

Conclusions: Neoadjuvant PD-1 blockade combined with platinum-based chemotherapy is associated with high pathological response rates and favorable surgical outcomes in patients with T4 and/or N2-N3 stage III NSCLC initially considered borderline resectable or unresectable. Biomarkers such as PD-L1 TPS, TMB, and co-mutation status may help identify patients most likely to benefit. These findings support the incorporation of neoadjuvant chemo-immunotherapy into treatment paradigms for locally advanced NSCLC and warrant further prospective validation.

SUNDAY, SEPTEMBER 7, 2025 - 12:00 - 13:15

MA01.05 Tislelizumab Plus Chemotherapy Followed by Surgery or Radiotherapy and Adjuvant Tislelizumab in Unresectable Stage III NSCLC

J. Liu, L. Tu, Y. Li, Y. Li, Z. Li, T. Wang, T. Wang, Q. Wu, L. Wang, X. Zhai, J. Dong, M. Fan, P. Tian, D. Pu, Y. Zhang, F. Luo, Y. Liu, J. Wang, F. Xu, Y. Lai, K. Wang, X. Zheng, G. Che
West China Hospital, Sichuan University, Chengdu/CN

Introduction: With neoadjuvant chemoimmunotherapy followed by surgery providing significant high pCR/MPR rates and survival benefit for resectable NSCLC, the current "Pacific Mode" of consolidation immunotherapy (IO) after chemoradiation for initially unresectable stage III NSCLC is being challenged. IO-based induction therapy may provide more survival benefit, partly by enabling surgery. However, the specific treatment modalities and beneficiary populations remain unclear. In this trial, we assessed induction tislelizumab (TIS) + chemo, followed by surgery or radiotherapy (RT), and TIS ± chemo as adjuvant therapy in unresectable stage III NSCLC to answer these questions. Here are the preliminary results.

Methods: This phase 2 study enrolled patients with histologically confirmed stage III NSCLC (per AJCC 8th edition) deemed initially unresectable based on at least one of the following criteria: (1) T4 tumors invade vital organs precluding R0 resection, (2) multi-station N2 metastases or N2 metastases fused into masses, and (3) N3 metastases. N2/N3 status was confirmed by PET/CT or pathology. Patients received 2-4 cycles of induction TIS plus nab-paclitaxel and platinum. Post-induction, MDT assessment will guide treatment with surgery or RT, followed by adjuvant TIS ± chemo for up to 1 year. The primary endpoint was 1-year EFS rate. Secondary endpoints included surgery rate, pCR, MPR and safety. The planned sample size was 55.

Results: As of March 14, 2025, 28 patients were enrolled, with 28.6% classified as stage IIIA, 46.4% stage IIIB, and 25.0% stage IIIC. 13 patients have completed induction therapy and post-induction MDT assessment, with an ORR of 100%. 3 patients (23.1%) underwent RT and 10 (76.9%) underwent surgery. All surgery patients achieved R0 resection; pCR and MPR rates were 60.0% (6/10) and 90.0% (9/10), respectively. Clinical and pathological downstaging occurred in 76.9% (10/13) and 90% (9/10) of patients. Specifically, patients who received 4 cycles of induction therapy exhibited numerically higher pCR and MPR rates (100% [4/4] for both) compared to those who received 3 cycles (33.3% [2/6] and 83.3% [5/6]), while the ORR was the same in both subgroups (100%). Among 28 patients enrolled, grade ≥3 TRAEs occurred in 7 (25.0%) patients, with frequency of ≥10% being hematotoxicities. No new safety signals were identified.

Conclusions: Induction tislelizumab plus chemo demonstrated preliminary promising antitumor activity with a tolerable safety profile in stage III NSCLC. A notable proportion of patients were enabled to receive radical surgery and attained good pathological response. Recruitment is ongoing, and efficacy and safety will be continuously monitored.

[1]Memorial Sloan Kettering Cancer Center, New York City/NY/USA ,[2]University of Washington, Seattle/WA/USA ,[3]University of Freiburg, Freiburg/DE

Introduction: More than half of patients with unresected stage III non-small cell lung cancer (NSCLC) progress within 2 years after treatment with concurrent chemoradiation (cCRT) and durvalumab consolidation. Interleukin (IL)-1β signaling has been implicated in treatment resistance and tumor progression in NSCLC. We prospectively evaluated the addition of canakinumab, a human monoclonal IL-1β antibody, to cCRT and durvalumab consolidation in patients with unresected stage III NSCLC.

Methods: CHORUS was a single-arm, open label phase I/II trial that enrolled unselected patients with unresected stage III NSCLC (NCT04905316). Canakinumab was administered as a subcutaneous injection (200mg every 3 weeks) starting within 5 days of cCRT for up to 3 cycles, and then was administered intravenously (200mg every 4 weeks) with durvalumab consolidation for up to 12 additional cycles. Concurrent chemoradiation included conventionally fractionated radiation (60 Gy in 30 fractions) with platinum-doublet chemotherapy. Durvalumab consolidation was administered as standard of care. The primary objective was to improve the 2-year progression-free survival (PFS) compared to the historical rate of 46%, using a one-sided test based on the Kaplan-Meier method. Patients were evaluable for the primary endpoint if they received ≥1 cycle of consolidation with canakinumab plus durvalumab. Response was per RECIST 1.1 criteria and was initially evaluated 4 weeks post-cCRT, then every 3 months.

Results: Between 11/2021 and 4/2022, 41 patients were enrolled, 37 started protocol therapy, and 32 patients were evaluable for the primary endpoint. The median follow-up was 24.6 months (95% CI 21.2, 27.3). The median age was 70 years, 56% (n=18) of patients were female, 66% (n=21) were ECOG 0, 88% (n=28) had a smoking history and 59% (n=19) had adenocarcinoma histology. Most patients had stage IIIB (n=14, 44%) or IIIA (n=10, 31%) disease. PD-L1 expression was known for 29 patients (91%) of which 48% (n=14) were PD-L1 <1% and 28% (n=8) were PD-L1 ≥ 50%. Most patients, 91% (n=29), received at least 2 doses of canakinumab concurrent with cCRT. Patients received a median of 7 (range: 1-12) cycles of canakinumab consolidation. An objective response to canakinumab + cCRT was observed in 74% (n=23) of patients on initial imaging post-cCRT and prior to consolidation. In total, an objective response was seen in 81% (n=26) of patients. The 12- and 24-month PFS rates were 75% (95% CI 61% - 93%) and 67% (95% CI 52% - 88%), respectively. The 12- and 24-month overall survival rates were 93% (95% CI 84% - 100%) and 73% (57% - 92%), respectively. There were no canakinumab treatment-related deaths. Grade 3/4 (n=7) canakinumab related toxicities occurred most commonly during cCRT and included grade 3 febrile neutropenia (n=1), neutropenia (n=4), lymphopenia (n=1) and grade 4 neutropenia (n=1). Grade 3 (n=3) canakinumab related toxicities occurring during durvalumab consolidation included lung infection (n=1), fatigue (n=1) and hypertension (n=1).

Conclusions: In this phase I/II trial, canakinumab with concurrent chemoradiation and durvalumab consolidation in unresected stage III NSCLC met the primary endpoint of improving 2-year PFS to > 46%, with acceptable safety, suggesting a possible new therapeutic approach for this patient population.

Introduction: Patients with locally advanced unresectable stage III non-small cell lung cancer (NSCLC) receive concurrent chemoradiotherapy (cCRT) as standard of care (SOC) followed by consolidation treatment with PD-L1 inhibition. BNT116, an intravenously administered, unmodified RNA-based lipoplex cancer immunotherapy, is composed of six mRNAs, each encoding a tumor-associated antigen frequently expressed in NSCLC: CLDN6, KK-LC-1, MAGE-A3, MAGE-A4, MAGE-C1, or PRAME. Preliminary results suggest a well-tolerated safety profile for BNT116 alone and in combination with cemiplimab. We present preliminary data for BNT116 plus cemiplimab in patients with advanced NSCLC after cCRT.

Methods: The open label, multi-cohort Phase I LuCa-MERIT-1 trial (NCT05142189) aims to determine the safety (treatment-emergent adverse events [TEAEs]) and clinical activity of BNT116, alone or in combination with immunotherapy or chemotherapy. This cohort will evaluate BNT116 plus cemiplimab for up to 12 months in patients with advanced NSCLC with previous SOC cCRT. BNT116 is administered weekly for the first 6 weeks, followed by once every 3 weeks. Cemiplimab is administered concomitantly every 3 weeks. Biomarker analysis includes immunogenicity (ELISpot), cytokines (MSD/ELISA), ctDNA (Avenio ctDNA Surveillance), and PD-L1 (immunohistochemistry).

Results: As of 01MAR2025, 20 patients (median age 67.5 years; range 42-82, 30.0% ECOG PS 0, 70.0% ECOG PS 1, 13 patients [65.0%] with PD-L1 tumor proportion score <50.0%) received BNT116 plus cemiplimab (median follow-up time 6.3 months; range 2-13). Eleven patients (55.0%) discontinued treatment, five (25.0%) due to adverse events (Table). All patients experienced treatment-related adverse events (TRAEs) to BNT116, and 15 patients (75.0%) experienced TRAEs to cemiplimab. Four patients (20.0%) experienced serious TRAEs to BNT116 (cytokine release syndrome in two patients and pneumonitis in two patients, three patients resolved without sequelae and one patient was recovering at the timepoint of reporting). No fatal TEAE was observed. BNT116 plus cemiplimab treatment led to tumor control or continued reduction in tumor size in most patients with a 6-month event-free survival (EFS) rate of 72.1% (95% CI 45.0-87.4) and an overall survival (OS) rate of 95.0% (95% CI 69.5-99.3). Cytokine analysis showed that patients mounted a strong type 1 interferon response, as expected based on the mode-of-action of BNT116.

Conclusions: BNT116 plus cemiplimab demonstrated a manageable safety profile dominated by short lasting, mostly mild-to-moderate cytokine-induced symptoms, comparable to patients who had not received prior cCRT, and showed no increase or recall of radiotherapy-related adverse events. Promising EFS and OS rates were observed. Updated safety, clinical activity, and biomarker data will be presented.

Table: Safety

Patients with reported TEAE, n (%)	N=20
Treatment discontinuation	**11 (55.0%)**
▪ completed per protocol	3 (15.0%)

MA01.08 Sequential Chemo-SAbR Following by Immunotherapy in Unresectable LA-NSCLC Unfit for Concurrent ChT-RT According to the START-NEW-ERA Trial

P. Anselmo[1], M. Casale[1], G.A. Viani[2], C. Zannori[3], F. Loreti[4], B. Enrico[5], A. Guida[3], M. Nunzi[5], S. Francesconi[6], M. Italiani[1], F. Trippa[1], F. Arcidiacono[1]
[1]Radiotherapy Oncology Centre "S.Maria" Hospital, Terni/IT ,[2]Radiotherapy Service, Hospital das Clinicas of the Sao Paulo State University (UNESP), Medical School, Botucatu, Botucatu/BR ,[3]Oncology Centre "S.Maria" Hospital, Terni/IT ,[4]Nuclear Medicine Centre "S.Maria" Hospital, Terni/IT ,[5]Radiology Centre "S.Maria" Hospital, Terni/IT ,[6]Pathology Centre "S.Maria" Hospital, Terni/IT

Introduction: The PACIFIC trial introduced a new treatment paradigm by introducing immunotherapy (IO) after concurrent chemo-radiotherapy (ChT-RT). The PACIFIC 6 shown safety profile in a frailer population. However there is a lack of data of IO consolidation after stereotactic ablative radiotherapy (SAbR). This is a single arm phase 2 trial (Clinical trials.gov NCT05291780) to assess efficacy and safety of SAbR in unresectable LA-NSCLC patients unfit for concurrent ChT-RT (1). Here we report clinical outcomes of SAbR in LA-NSCLC patients treated with radical-intent based on PACIFIC trial.

Methods: Between December 31, 2015 and 17 March 31, 2025 115 LA-NSCLC patients were enrolled. After 2017 PD-L1 ≥1% fit for ChT patients were treated according to this scheme: ChT + SAbR + IO. Up today 32 LA-NSCLC patients were enrolled. The tumor volume included primary tumor (T) and any regionally positive node/s (N). The co-primary study endpoints were LC and safety.

Results: The median age was 73 years (range, 52-78). Histology was adenocarcinoma (ADC) and squamous cell carcinoma (SCC) and in 9 (60%) and 6 (40%), respectively. The stage was IIIA, IIIB and IIIC in 7 (44%), 6 (37%) and 3 (19%) patients, respectively. Median prescribed dose was 45 Gy (range, 40-50) and 40 Gy (35-50) in 5 daily fractions to T and N, respectively. After a median follow-up of 20 months (range, 9-67), 5 (16%) patients had experienced local recurrence (LR) at a median time of 13 months (range, 7-34). The median LR-free survival (FS) was 34 months (95% CI, 14 to 34). The 1-, 2- and 4- year LR-FS rates were 92±8%, 72±14% and 48±22%, respectively. At last follow-up, 23 (74%) patients were alive. Median overall survival (OS) was 50 months (95% CI, 31-55). The 1, 2, and 4-year OS rates were 92±5%, 70±8% and 51±9%, respectively. 4 (27%) patients developed distant progression (dP). The median dP-FS was not reached (95% CI, 14 to not reached). The 1, 2, and 4-year dP-FS rates were 100%, 50±19% and 50±19%, respectively. 7 patients had disease recurrence, 4 and 3 during and after completion of Durvalumab. The pattern of disease recurrence was distant and local in 4 and 3 patients, oligo-metastatic disease recurrence in 9 patients. 3 (10%) discontinued IO due to esophageal and lung G3 toxicity.

Conclusions: To our knowledge this is the first trial to report efficacy and safety of ChT-SAbR-IO. LA-NSCLC patients treated had optimal LC and promising OS with low rate of G3 toxicity. Our early outcomes would suggest the feasibility of SAbR as sequential schedule approach in LA-NSCLC patients unfit for concurrent ChT-RT.

MA02 NEW TREATMENT STRATEGIES IN OTHER THAN EGFR-POSITIVE TUMORS
SUNDAY, SEPTEMBER 7, 2025 - 12:00 - 13:15

MA02.01 Contemporary Landscape of Acquired Resistance to Next-Generation ALK Inhibitors: Paired Pre-/Post-Treatment Biopsy Analysis

S. Waliany, A. Do, J. Peterson, J. Liang, J.F. Gainor, J.J. Lin
Massachusetts General Hospital Cancer Center, Boston/MA/USA

Introduction: Next-generation ALK tyrosine kinase inhibitors (TKIs) have supplanted the first-generation (1G) TKI crizotinib as first-line (1L) treatment for patients with ALK-rearranged advanced lung cancer. Data are lacking on the landscape of mechanisms of acquired resistance (AR) that emerge after 1L next-generation TKIs, without prior crizotinib. Here, we report the largest analysis, to our knowledge, of paired pre- and post-ALK TKI biopsies evaluating AR.

Methods: This retrospective study included patients treated with second-generation (2G; alectinib, brigatinib, ceritinib) and/or third-generation (3G; lorlatinib) ALK TKIs with paired (pre- and post-TKI) biopsies assessed with next-generation sequencing (NGS). Pre-treatment biopsies were obtained immediately before TKI of interest. Alteration frequencies were compared between biopsies post- versus pre-TKI (McNemar's exact test) and with versus without prior crizotinib (Chi-Square or Fisher's exact test).

Results: We identified 101 patients with 152 paired biopsies. Sixty-eight patients had 84 paired pre/post-2G TKI biopsies. Acquired ALK resistance mutations were identified in 8 (61.5%) post-2G TKI biopsies with prior crizotinib versus 24 (33.8%) without prior crizotinib (p=0.07). Recurrent acquired gene alterations in ≥5% of post-2G TKI biopsies included TP53 (11.5%), SETD2 (11.1%), SMARCA4 (8.8%), MET (7.1%; amplification: 4.8%; VUS: 2.4%), SMAD4 (6.5%), EGFR (6.0%; amplification: 1.2%; VUS: 4.8%), KEAP1 (5.9%), NOTCH2 (5.6%), and CDKN2A/B (5.4%), with similar frequencies with versus without prior crizotinib (Table). Among patients without prior crizotinib, MET amplification was numerically more frequent on post- versus pre-2G TKI biopsies (5.6% vs 1.4%, p=0.25). Acquired alterations were not identified in ALK or other genes in 20 (23.8%) post-2G TKI biopsies. Sixty patients had 68 paired pre/post-lorlatinib biopsies. Acquired ALK mutations were identified in 12 (37.5%) post-lorlatinib biopsies with prior crizotinib versus 5 (13.9%) without prior crizotinib (p=0.048). Recurrent acquired gene alterations in ≥5% of post-lorlatinib biopsies included CDKN2A/B (15.2%), TP53 (13.4%), MDM2 (13.0%), MET (11.8%; all amplifications), EGFR (7.4%; amplification: 4.4%; VUS: 2.9%), and NF1 (6.5%). Among patients without prior crizotinib, MET amplification was more frequent on post- versus pre-lorlatinib biopsies (22.2% vs 2.8%, p=0.016). Acquired gene alterations were not identified in 23 (33.8%) post-lorlatinib biopsies.

Conclusions: First-line versus post-crizotinib use of next-generation ALK TKIs was associated with lower frequency of acquired ALK mutations, implicating greater role for off-target AR. MET amplification represents a recurrent off-target AR mechanism and highlights the critical role for post-TKI biopsies to enable consideration of ALK/MET co-inhibition. NGS does not identify putative AR mechanisms for significant proportion of patients, emphasizing a need to investigate non-genomic AR mechanisms.

Table: Landscape of Acquired On-Target and Off-Target Genomic Alterations after Next-Generation ALK TKIs Per Paired Pre- and Post-TKI Analyses

Acquired Alterations after 2G ALK TKIs				Acquired Alterations after 3G ALK TKI (Lorlatinib)

Genes identified as having acquired alterations in ≥5% of post-2G TKI or post-3G TKI biopsies compared to the immediate pre-treatment biopsies per paired biopsy analyses are shown. Denominators represent the number of biopsies evaluated by next-generation sequencing assays that covered each respective gene.
*Acquired *ALK* mutations and *MET* amplification were mutually exclusive except in one post-2G TKI biopsy (with prior crizotinib).
§ All identified acquired *MET* mutations have unknown functional significance.
† All identified acquired *EGFR* mutations have unknown functional significance, except for one post-2G TKI biopsy (without prior crizotinib) with a potentially activating *EGFR* mutation (*EGFR* P596L) with concurrent *MET* amplification.
‡ Of the 43 patients with no identified acquired gene alterations (including in *ALK* or other genes), *ALK* fusion was not detected in three post-3G TKI biopsies (prior crizotinib: n=2, no prior crizotinib: n=1) and was not evaluated in one post-2G TKI (without prior crizotinib) and two post-3G TKI biopsies (without prior crizotinib).
Abbreviations: 2G, second-generation; 3G, third-generation; amp, amplification; criz, crizotinib; mut, mutation; TKI, tyrosine kinase inhibitor.

Introduction: Taletrectinib, an oral, potent, central nervous system-active, selective next-generation ROS1 inhibitor, demonstrated high and durable responses, robust intracranial activity, prolonged progression-free survival (PFS), favorable tolerability, and low rates of neurologic adverse events in a pooled analysis from the regional TRUST-I (NCT04395677) and global TRUST-II (NCT04919811) trials (Pérol M, et al. J Clin Oncol. 2025:epub April 3, 2025). With 5 months of additional follow-up since our last publication (Liu G, et al. J Thorac Oncol. 2024;19:S72), we report updated efficacy and safety in tyrosine kinase inhibitor (TKI)-naive and TKI-pretreated patients from the registrational arms of the TRUST-II trial evaluating the efficacy and safety of taletrectinib in patients with advanced ROS1+ non-small cell lung cancer (NSCLC).

Methods: TRUST-II is a global, multicenter, single-arm pivotal phase 2 study of taletrectinib 600 mg once-daily in patients with ROS1+ tumors and included 2 registrational NSCLC cohorts: 1) TKI naive, ≤1 line of chemotherapy, and 2) TKI pretreated, 1 prior ROS1 TKI, and ≤1 line of chemotherapy. The primary endpoint was objective response rate (ORR) by independent review committee per RECIST v1.1. Key secondary endpoints included duration of response (DOR), PFS, and safety.

Results: As of October 28, 2024, 105 patients were enrolled in TRUST-II registrational cohorts (median age: 57 years; 55% female; 55% never smoked); 47% were from North America/Europe. Among TKI-naive and TKI-pretreated patients, 16% and 32% had measurable baseline brain metastases, respectively. In 54 efficacy-evaluable TKI-naive patients, ORR was 85% (95% CI: 73, 93) and median DOR was not reached (NR). In 47 efficacy-evaluable TKI-pretreated patients, ORR was 62% (95% CI: 46, 75) and median DOR was 19.4 months (95% CI: 10.7, NR). Median PFS was NR in TKI-naive patients and 11.8 months (95% CI: 7.7, 20.6) in TKI-pretreated patients (Table). The most common treatment-emergent adverse events (TEAEs) among patients receiving taletrectinib 600 mg were increased ALT (67%), increased AST (65%), and diarrhea (58%). Rates of neurologic TEAEs were low (dysgeusia: 19%; dizziness: 18%) and mostly grade 1. TEAEs led to discontinuation in 9% of patients; most (11 of 15) were considered unrelated to taletrectinib.

Conclusions: With longer follow-up in a geographically diverse population, taletrectinib continues demonstrating high and durable objective responses and a favorable safety profile. Enrollment in TRUST-II is ongoing. Efficacy and safety of taletrectinib will be directly compared with crizotinib in an ongoing randomized head-to-head phase 3 trial in TKI-naive patients with locally advanced or metastatic ROS1+ NSCLC (NCT06564324).

Table: Responses in Evaluable Patients With *ROS1*+ NSCLC[a]

	TKI naive (n=54)	TKI pretreated (n=47)
ORR, % (95% CI)	85 (73, 93)	62 (46, 75)
Complete response, n (%)	4 (7)	5 (11)
Partial response, n (%)	42 (78)	24 (51)
Median DOR[b], months (95% CI)	NR (20.6, NR)	19.4 (10.7, NR)
Median PFS, months (95% CI)	NR (NR, NR)	11.8 (7.7, 20.6)

[a]Response-evaluable patients had received ≥1 dose of taletrectinib 600 mg and had ≥1 measurable lesion at baseline.
[b]DOR was calculated for patients with confirmed responses.
DOR, duration of response; NR, not reached; NSCLC, non-small cell lung cancer; ORR, objective response rate; PFS, progression-free survival; TKI, tyrosine kinase inhibitor.

Introduction: Repotrectinib is a next-generation ROS1 and TRK tyrosine kinase inhibitor (TKI) approved for treatment of adult patients with locally advanced/metastatic ROS1+ NSCLC and adult or pediatric patients (≤12 y) with locally advanced/metastatic NTRK+ solid tumors based on the pivotal phase 1/2 TRIDENT-1 trial (NCT03093116). Herein, long-term follow-up data are reported for 2 ROS1+ NSCLC cohorts and safety in all patients treated at the recommended phase 2 dose (RP2D).

Methods: Patients with ROS1+ NSCLC were assigned to 1 of 4 cohorts based on treatment history. In phase 2, patients received repotrectinib 160 mg QD for 14 days, then 160 mg BID. Primary endpoint of phase 2 was confirmed objective response rate (cORR) by blinded independent central review per RECIST v1.1. Secondary endpoints included duration of response (DOR), progression-free survival (PFS), overall survival (OS), intracranial ORR (icORR), and safety. Safety assessments included patients treated at the RP2D across all study cohorts.

Results: At data cutoff of September 3, 2024, median follow-up was 44.6 months (range, 34.7-87.1) in the TKI-naïve cohort (n=71) and 42.0 months (range, 34.7-79.1) in the 1 prior TKI and no chemo cohort (n=56). In the TKI-naïve cohort, cORR was 79% (95% CI, 68-88); median DOR was 36.8 months (95% CI, 27.4-not estimable [NE]), and median PFS was 31.1 months (95% CI, 21.9-NE). Among TKI-naïve patients with measurable brain metastases at baseline (n=9), icORR was 89% (95% CI, 52-100). In the 1 prior TKI and no chemo cohort, cORR was 41% (95% CI, 28-55); median DOR was 17.8 months (95% CI, 7.5-31.4), and median PFS was 8.6 months (95% CI, 5.5-14.5). Among patients in this cohort with measurable brain metastases at baseline (n=13), icORR was 38% (95% CI, 14-68). Of all patients treated at the RP2D (n=502), the most common treatment-emergent adverse event (TEAE) was dizziness (64%). Grade ≥3 treatment-related adverse events (TRAEs) occurred in 164 (33%) patients. TRAEs leading to dose reduction or treatment discontinuation occurred in 39% and 4% of patients, respectively. Additional data will be presented, including OS, subsequent therapies, and efficacy outcomes in an expanded population.

Conclusions: Repotrectinib continued to demonstrate durable efficacy and intracranial activity in patients with ROS1+ NSCLC in the TKI-naïve and the 1 prior TKI and no chemo cohorts of TRIDENT-1, with median follow-up of ≥42 months. Safety outcomes were consistent with previous reports.

Table: Efficacy of Repotrectinib in Patients With *ROS1+* NSCLC

ROS1+ NSCLC cohorts	TKI-naive (n=71)	1 TKI and no chemo (n=56)
cORR (CR + PR) per BICR,[a] n (%) [95% CI]	**56 (79) [68–88]**	**23 (41) [28–55]**
CR, n (%)	10 (14)	4 (7)
PR, n (%)	46 (65)	19 (34)
SD, n (%)	11 (15)	21 (38)
PD, n (%)	2 (3)	9 (16)
Not evaluable, (%)	0	2 (4)
Duration of response		
Events, n (%)	25 (45)	15 (65)
Median, months (95% CI)	36.8 (27.4–NE)	17.8 (7.5–31.4)
Progression-free survival		
Events, n (%)	34 (48)	38 (68)
Median, months (95% CI)	31.1 (21.9–NE)	8.6 (5.5–14.5)
Efficacy in patients with measurable brain metastases at baseline[b]	**(n=9)**	**(n=13)**
Intracranial ORR per BICR, % (95% CI)	**89 (52–100)**	**38 (14–68)**
CR, n (%)	4 (44)	0
PR, n (%)	4 (44)	5 (38)
Efficacy in patients with *ROS1+* G2032R NSCLC[c]	-	**(n=17)**
cORR, % (95% CI)	-	59 (33–82)
Median duration of response, months (95% CI)	-	7.6 (3.7–NE)

BICR, blinded independent central review; cORR, confirmed objective response rate; CR, complete response; NE, not estimable; NSCLC, non-small cell lung cancer; PD, progressive disease; PR, partial response; RECIST, Response Evaluation Criteria in Solid Tumors; *ROS1+*, *ROS1* fusion–positive; SD, stable disease; TKI, tyrosine kinase inhibitor.
[a]In the TKI-naive cohort, 2 patients (3%) had missing data; in the 1 TKI and no chemo cohort, 1 patient (2%) had missing data.
[b]Intracranial cORR was assessed by modified RECIST v1.1 in evaluable patients in the phase 2 portion of study.
[c]Among all TKI-pretreated patients across EXP 2-4.

Introduction: NTRK gene fusions are oncogenic drivers in a variety of cancers including lung cancer. Larotrectinib is the first-in-class, highly selective, central nervous system (CNS)-active TRK inhibitor approved for tumor-agnostic use in TRK fusion cancer. Here, we report an additional year of follow-up after the previously published larotrectinib efficacy and safety data, as well as a biomarker analysis, in patients with TRK fusion lung cancer.

Methods: Patients with TRK fusion lung cancer treated with larotrectinib in 2 clinical trials (NCT02122913 and NCT02576431) were included. Larotrectinib was administered at 100 mg twice daily. Response was assessed by an independent review committee (IRC) per Response Evaluation Criteria in Solid Tumors version 1.1. Tumor DNA or circulating tumor DNA (ctDNA) next-generation sequencing (NGS) was performed before (baseline) and after larotrectinib initiation. On-target NTRK (solvent front, gatekeeper, and xDFG) mutations and COSMIC-classified tier 1/2 off-target alterations were identified. Secondary (acquired) resistance was defined as the development of resistance after meaningful clinical benefit (complete response [CR]/partial response [PR]/stable disease [SD] ≥4 months). The data cutoff was July 20, 2024.

Results: At data cutoff, 32 patients with a median age of 56 years (range 25-81) with TRK fusion lung cancer were enrolled, including 12 with known CNS metastases at baseline. Patients had received a median of 2 prior lines of systemic therapies; 1 patient was systemic treatment-naïve in the metastatic/unresectable setting. The overall response rate was 69% (95% confidence interval [CI] 50-84): 4 CR, 18 PR, 6 SD, 2 progressive disease [PD], and 2 not evaluable. The median time to response was 1.8 months (range 1.5-7.3). Median duration of response was 34 months (95% CI 13-not estimable [NE]) with a median follow-up of 37 months. Median progression-free survival was 22 months (95% CI 10-39) with a median follow-up of 38 months. Median overall survival was 41 months (95% CI 17-NE) with a median follow-up of 46 months. Median duration of treatment was 20 months (range 2-75). At data cutoff, 8 (25%) patients remained on treatment: 7 had responded and 1 was not evaluable for response. Treatment-related adverse events (TRAEs) were predominantly Grade 1/2. Grade 3/4 TRAEs were reported in 10 (31%) patients. One patient discontinued treatment due to TRAEs (increased alanine aminotransferase, aspartate aminotransferase, and gammaglutamyl transferase). Secondary larotrectinib resistance was observed in 5 patients with valid post-baseline ctDNA; acquired alterations were identified in 2 of these patients. An acquired on-target alteration was identified in 1 patient (NTRK1 F589L). An acquired off-target alteration was identified in 1 patient (TP53 C238F). Acquired on- and/or off-target alterations were identified in 3 other patients that did not have PD by IRC assessment (TP53 G245V in 1 patient, NTRK1 F589L in 1 patient; and both NTRK1 F589L and KRAS G12D in 1 patient).

Conclusions: Larotrectinib continues to demonstrate rapid and durable responses, extended survival benefit, and a favorable safety profile in patients with advanced TRK fusion lung cancer. These results support the wider adoption of NGS panels that incorporate NTRK gene fusion detection.

Introduction: Dabrafenib plus trametinib (D+T) is the standard first-line (1L) treatment of advanced BRAF V600E mutated non-small cell lung cancer (NSCLC). To date, the role of liquid biopsy monitoring activity for predicting outcomes of 1L D+T in advanced BRAF V600E mutated NSCLC has not been assessed.

Methods: We conducted a prospective multicentric study in 25 Italian Centers aimed at exploring the role of liquid biopsy in advanced BRAF V600E mutated NSCLC patients treated with 1L D+T. Plasma samples were collected before treatment start (t0), after 4 weeks (t1), every 4 weeks during the first 16 weeks of treatment and every 8 weeks until progression (PD). Digital droplet PCR (ddPCR) was performed to monitor BRAF V600E in plasma samples. Next-Generation Sequencing (NGS) analysis was conducted on plasma samples at t0 and PD.

Results: We enrolled 40 BRAF V600E mutated NSCLC patients treated with 1L D+T. Overall, 24 (60%) patients were male, median age was 71 years (Interquartile Range [IQR], 65-77), and 28 (70%) patients were smokers. D+T resulted in an Overall Response Rate of 43% (95% Confidence Interval [CI], 27-58) and a Disease Control Rate of 70% (95% CI, 56-84). After a median follow-up of 17.8 months (95% CI, 14.0-21.8), 24 (60%) patients progressed and 18 (45%) patients died. Median progression-free survival (mPFS) was 8.3 months (95% CI, 4.4- Not Reached [NR]) and median Overall Survival (mOS) was 21.1 months (95% CI, 8.6-NR).

ddPCR analysis at t0 revealed that ctDNA was positive for BRAF V600E in 24/39 (62%) evaluable patients (shedders), with a median variant allele frequency (AF) of 1.1% (IQR, 0.6-5.2). At NGS, baseline shedding was observed in 26/39 (67%) evaluable patients. Co-mutations were detected in NGS analysis at t0 in 19/26 (73%) shedders, with TP53 being the most frequent (14/26, 54%). Among baseline shedders evaluable for clearance at t1 (n=21), 17 (81%) cleared BRAF V600E. At PD, 11/20 (55%) evaluable patients had detectable BRAF V600E on ctDNA, eight of whom experienced an increase in AF. Among patients who experienced a biological PD (n=10), all of them had a radiologic/clinical PD with a median interval of 4.9 weeks (IQR 1.4-9.8). All the patients harbored a co-mutation at PD, and putative resistance mechanisms included mutations in NRAS, KRAS, TP53 and CNV in MET, EGFR, and ERBB2.

Among baseline shedders, higher BRAF V600E AF was associated with shorter PFS and OS: Cox Regression for continuous variable PFS HR 1.09 (95% CI, 1.02-1.17, p=0.013), OS HR 1.10 (95% CI, 1.02-1.18, p=0.010). Baseline EGFR and MET amp were associated with poor PFS (3.4 vs 10.3, p<0.001; 3.4 vs 10.3, p=0.018) and OS (3.4 vs NR, p<0.001; 3.7 vs NR, p=0.009). Clearance of BRAF V600E by t1 was associated with improved PFS (8.3 vs. 1.4 months, p<0.001) and OS (10.5 vs. 2.2 months, p<0.001).

Conclusions: Liquid biopsy might be a promising tool to predict the outcomes of 1L D+T in advanced BRAF V600E mutated NSCLC. The dynamics of ctDNA shedding provide potential early biomarkers of treatment response.

Introduction: Olomorasib, a potent and selective second-generation KRAS G12C inhibitor, has demonstrated promising antitumor activity and a manageable safety profile in KRAS G12C-mutant NSCLC in combination with pembrolizumab, a current first-line (1L) standard of care (SOC) for patients (pts) with NSCLC and PD-L1 expression ≥50%. Here we report results of an integrated analysis in 1L pts who received olomorasib plus pembrolizumab from the dose optimization cohorts in LOXO-RAS-20001 (Phase 1) and SUNRAY-01 (Phase 3).

Methods: Pts with advanced KRAS G12C-mutant NSCLC (ECOG PS 0-1) were randomized to olomorasib (50 or 100 mg, orally BID) with pembrolizumab (200 mg Q3W) and stratified based on PD-L1 expression (0-49% versus ≥50%). One prior cycle of pembrolizumab was allowed when timely initiation for treatment was medically indicated. Safety was assessed across all treated pts. ORR was assessed in the efficacy evaluable population, including pts with ≥1 post-baseline response assessment or who discontinued treatment before the first response assessment.

Results: As of 15 January 2025, 85 pts received olomorasib plus pembrolizumab including 14 pts (17%) who received 1 cycle of pembrolizumab prior to enrollment; 63% were PD-L1 ≥50%, 21% were PD-L1 1-49%, and 16% were PD-L1 <1% (1 pt unknown). With a median follow-up of 7.6 months (IQR: 5.5-9.5), any grade treatment-related adverse events (TRAEs) in ≥20% of pts were diarrhea (29%) and ALT/AST increased (26%/25%). The most common grade ≥3 TRAEs were ALT/AST increased (18%/14%), and diarrhea (7%). Hepatic events were overall manageable with dose adjustments and/or corticosteroids. TRAEs led to olomorasib dose reduction in 29% of pts and discontinuation of combination treatment in 9% of pts. The ORR was 71% in all pts (n=82) regardless of PD-L1 expression and 85% in pts with PD-L1 ≥50% who received olomorasib 100 mg BID (n=26). Responses were durable across all pts, as the median DOR was not yet reached and 6-month PFS rate was 77% (Table 1). Updated data will be presented.

Conclusions: In this merged dataset with double the number of 1L pts relative to previous presentations, olomorasib plus pembrolizumab continues to demonstrate a manageable safety profile and promising efficacy. These updated findings, including longer follow-up on LOXO-RAS-20001 pts, provide additional support for the ongoing Phase 3 SUNRAY-01 trial, comparing olomorasib (100 mg BID) plus pembrolizumab versus placebo plus pembrolizumab as 1L treatment in pts with KRAS G12C-mutant NSCLC and PD-L1 ≥50%.

Table. Response and Time-To-Event Endpoints in the Efficacy Evaluable Population

	Olomorasib (50 mg or 100 mg BID) + Pembrolizumab

Introduction: Kirsten rat sarcoma (KRAS) G12D mutation ranks among the most prevalent oncogenic drivers in human cancers, occurring in approximately 4% of NSCLC cases and associated with poorer prognosis. To date, no targeted therapies for KRAS G12D have been approved, leaving a significant unmet medical need. GFH375 is a potent, highly selective, and orally bioavailable KRAS G12D inhibitor that showed encouraging preliminary clinical efficacy (presented in ASCO 2025). Herein, we report the cumulative safety data of GFH375 and preliminary efficacy in NSCLC from the phase I/II study (NCT06500676).

Methods: Eligible patients (pts) who had advanced KRAS G12D mutant solid tumors and failed prior standard therapies were enrolled and received GFH375 once daily (QD) at dose levels 100, 200, 400, 600, 750, 900 mg, or twice daily (BID) 300 mg. Key study endpoints included safety and anti-tumor activities according to RECIST v1.1.

Results: 142 pts were enrolled, including 28 NSCLC, 85 pancreatic ductal adenocarcinoma (PDAC) and 29 other solid tumors. The median exposure time of GFH375 was 2.2 (range: 0.2-11.3) months as of 17-Jun-2025. The most common treatment-related adverse events (TRAEs) (reported in ≥20% pts) were diarrhea, vomiting, nausea, anemia, decreased appetite, neutrophil count decreased, white blood cell count decreased, aspartate aminotransferase increased, asthenia, hypoalbuminemia and alanine aminotransferase increased, primarily grade 1 or 2. Treatment-related grade 3/4 AEs and SAEs occurred in 27.5% (39/142) and 7.7% (11/142) of pts. 11 pts (7.7%) had dose reduction, and 6 (4.2%) discontinued due to TRAEs. No treatment-related death. 28 pts with NSCLC (100% adenocarcinoma, 53.6% male, and median age 61) were treated. 17 (60.7%) pts were never-smoker. 22 pts had baseline PD-L1 TPS reported: 13 (59.1%), 8 (36.4%) and 0 pts had TPS <1%, 1%-49% and ≥50%, respectively. All pts had metastatic disease at baseline. 64.3% (18/28) of pts received at least 2 prior lines of systemic therapies and 96.4% (27/28) received anti-PD1/PD-L1. As of 15-Jul-2025, the median follow-up time was 4.5 (range: 1.8-12.2) months. Tumor response was observed at all dose levels. Among the 26 evaluable pts, objective response rate (ORR) was 57.7% (15/26, 90%CI: [39.8%, 74.2%]) and disease control rate (DCR) 88.5% (23/26, 90%CI: [72.8%, 96.8%]). At 600 mg QD, ORR was 68.8% (11/16, 90%CI: [41.3%, 89.0%]) and DCR was 93.8% (15/16, 90%CI: [69.8%, 99.8%]). Among the 18 pts with baseline ctDNA test, 9 had detectable KRAS G12D mutation. Co-mutation genes included KEAP1 (33.3%, 6/18), STK11 (33.3%, 6/18), TP53 (27.8%, 5/18) and PIK3CA (11.1%, 2/18). Conclusion: GFH375 is well tolerated. As monotherapy, it demonstrates promising anti-tumor activity in NSCLC pts with KRAS G12D mutations, warranting further clinical development.

MA02.08 Upfront Management of Brain Metastases (BM) in Oncogene-Addicted NSCLC Treated With Targeted Therapies: An EORTC Survey

A. Ortega-Franco[1], I. Houda[2], M. Brandão[3], T. Pierret[4], L. Kaesmann[5], N. Gjaj-Levra[6], J. Remon[7], T. Berghmans[3], A-M. Dingemans[8], C. Faivre-Finn[1], L. Hendriks[9]
[1]The Christie NHS Foundation Trust, Manchester/GB ,[2]VU Medical Center - Cancer Center Amsterdam, Amsterdam/NL ,[3]Institut Jules Bordet - Hôpital Universitaire de Bruxelles, Brussels/BE ,[4]Louis Pradel Hospital- Hospices Civils of Lyon, Lyon/FR ,[5]LMU University Hospital, Munich/DE ,[6]IRCCS Sacro Cuore Don Calabria Hospital - Cancer Care Center, Verona/IT ,[7]Gustave Roussy, Villejuif/FR ,[8]Erasmus MC Cancer Institute - University Medical Center, Rotterdam/NL ,[9]Maastricht UMC+, Maastricht/NL

Introduction: BM are frequent in patients with oncogene-addicted non-small cell lung cancer (NSCLC). Although patients with untreated asymptomatic BM are increasingly allowed in registrational trials, data regarding intracranial efficacy of targeted therapies (TT) in this setting is limited resulting in a lack of evidence for decision-making.

Methods: A web-based survey was distributed among EORTC and ESTRO members to understand the preferred management of untreated asymptomatic BM (asBM) and symptomatic BM (sBM) in patients with oncogene-addicted NSCLC.

Results: Responses from 166 participants were received (57.2% medical oncologists, 41.0% radiation oncologists): 81.9% of the participants routinely screen for BM, and 98.9% have access to local brain therapies such as stereotactic radiotherapy. Access to TT differed across oncogenes: EGFR and ALK had the highest (~ 97%) and NTRK and HER2 the lowest (~ 60%). Overall, the preferred treatment for asBM were TT (68.8%) while it was local therapy (42.9%) for sBM (Table 1), but there were differences according to the intracranial objective response rate (icORR) of TT, oncogene and participants' specialty. TT were grouped according to icORR: 39.6%, 26.4% and 32.0% of participants had access to TT with 'high', 'medium' and 'low/unknown' icORR (defined as icORR ≥75%, 50-75%, <50%/unknown respectively). In asBM, TT were the preferred treatment across icORR groups, with a higher % in the 'high' versus (vs) 'low/unknown' (75.3% vs 63.6%). For sBM, local therapy was more often preferred, with a higher % for low/unknown' vs 'high' icORR (48.3% vs 37.1%). Importantly, in sBM, TT were preferred in 27.1% vs 11.9% of participants in the 'high' vs 'low/unknown' icORR groups. When oncogenes were grouped in 'Classic' (ALK/EGFR/ROS1) vs 'Emergent'; the preferred treatment for asBM were TT (80.9% vs 61.5%). For sBM, the preferred treatment was local therapy + TT (34.7%) in 'Classic' vs local therapy alone (49.2%) in 'Emergent' oncogenes. The factors that influenced decision-making were icORR for TT (85.5%), disease burden (81.3%), but also participants' specialty. Medical oncologists more often preferred TT for asBM compared to radiation oncologists (81.8% vs 50.9%). Almost half (47.8%) of participants do not give TT concurrently with cranial radiotherapy, 7.9% are unsure, but no significant differences were found across oncogenes/ specialty.

Conclusions: Management of BM is different for asBM vs sBM, but also for the different oncogenes (probably related to available evidence and icORR of TT) and across specialities. Research efforts should be directed to improve evidence-based decision-making via dedicated clinical trials and/or prospective data collection.

Table 1. Preferred management of symptomatic and asymptomatic brain metastases in the overall analysis (all) and subgroup analysis by medical specialty, targeted therapy (TT) intracranial response rate (icORR) and oncogene type.

	All	Medical Specialty		Targeted therapy icORR			Oncogene

Introduction: Circulating tumor (ct)DNA is a powerful prognostic marker in early-stage NSCLC, however detecting ctDNA in the blood of stage I non-small cell lung cancer (NSCLC) patients has been limited, especially for adenocarcinomas. The ctDNA Lung DETECT study evaluated perioperative ctDNA and recurrence-free survival (RFS) in patients with clinical stage I NSCLC (NCT05254782), and previously reported suboptimal sensitivity using a first-generation whole exome sequencing (WES) based tumor-informed assay (Khan et al, ASCO 2024). Foresight CLARITY (Foresight Diagnostics, Aurora CO) tracks tumor-specific variants identified from whole genome sequencing (WGS), with 95% LOD of 0.3 x 10-6 (Cabel et al, ESMO 2024). Here we applied this ultrasensitive approach to patients from ctDNA Lung DETECT to test if it can improve MRD detection in stage I NSCLC, focusing on peri-operative detection, association with RFS, lead time, and ctDNA clearance with adjuvant therapy.

Methods: Patients with stage I NSCLC planned for resection at University Health Network consented to banking of surgical tissue and blood pre-operatively, 3-6 weeks post-resection (MRD landmark), and one-year post-operatively. Bespoke panels targeting up to 5000 somatic variants identified via WGS of FFPE tumor tissue were generated. Blood plasma samples were analysed for MRD, with the laboratory blinded to outcomes. Outcomes included ctDNA detection, sensitivity and association with RFS.

Results: We profiled 140 blood and tissue specimens from 30 patients with clinical stage I NSCLC (pathologic stage: I-16, II-8, III/IV-6). Most had adenocarcinoma (83%), 57% received adjuvant therapy and 37% had cancer recurrence. Bespoke assays were successfully generated for 100% of patients and applied to plasma samples before and after resection. ctDNA was detected in 67.9% of preoperative and 37.9% of postoperative samples, substantially higher than the previously reported rate in the full ctDNA Lung DETECT study with a first-generation assay (22.7% and 2.0%, respectively). Preoperative ctDNA detection rates in pathologic stage IA and IB were 33% and 71%, respectively; 75% of these had adenocarcinoma. Landmark MRD was detectable in 55% of relapse cases, higher than the 10% detection rate reported previously with a first-generation assay (Khan et al, ASCO 2024). This included patients with stage I disease and MRD levels as low as 1.0x10-6. Both preoperative ctDNA and postoperative MRD were associated with a trend to shortened RFS, even though a significant fraction of MRD positive patients later received adjuvant chemotherapy or osimertinib (ongoing). MRD detection at one year was strongly associated with RFS (P=0.0001, HR 10.7, 95% CI 2.4-48). In patients with recurrence and MRD at the landmark, the median lead-time to recurrence was 10 months (range: 4-24, n=6). Moreover, 92.9% (13/14) of samples collected within 12 months of relapse had detectable MRD. Finally, MRD clearance was observed in a subset of patients receiving adjuvant therapy.

Conclusions: Ultrasensitive MRD detection using a WGS tumor-informed assay demonstrated higher rates of MRD detection in clinical stage I patients than prior reports using a first-generation assay. MRD detection was associated with RFS and provided clinically relevant lead times. These results support exploring ultrasensitive ctDNA MRD-guided treatment strategies in stage I NSCLC.

MA03.02 Clinical Performance of a Tumor Informed Whole Genome Based ctDNA Assay for Predicting Recurrence in Early-Stage Resectable NSCLC

G. Becharano[1], S. Sudhaman[2], A. Wray[2], C. Carson[2], S. Velichko[2], R.K. Kollipara[2], J.B. Ortiz[2], M. Malhotra[2], E. Kalashnikova[2], M. Krainock[2], H. Sethi[2], M.C. Liu[2], A. Aleshin[2], E. Podgaetz[1], G. Schwartz[1]
[1]Baylor Scott and White Research Institute, Dallas/TX/USA ,[2]Natera, Inc., Austin/TX/USA

Introduction: Circulating tumor DNA (ctDNA) is a clinically validated biomarker for detecting molecular residual disease (MRD) and guiding treatment decisions in non-small cell lung cancer (NSCLC). Early-stage, resectable NSCLC exhibits an aggressive biology despite limited radiographic burden. This creates a critical need for sensitive tools to inform prognosis and guide therapeutic strategies. Therefore, we assessed the clinical performance of the SignateraTM Genome assay to determine its prognostic value for risk stratification in this patient population.

Methods: We performed a retrospective analysis of residual plasma samples from a real-world dataset. Patients who underwent curative-intent surgery for stage I-III resectable NSCLC between September 25, 2017, to September 3, 2024, were included. Signatera Genome assays were designed from the respective patients' matched tumor and normal whole genome sequencing (WGS) data. ctDNA was subsequently tracked in the patients' longitudinal blood samples, which were collected postoperatively until recurrence/end of follow-up. The MRD window was defined as 2 months from surgery and prior to adjuvant therapy. The correlation between landmark-adjusted ctDNA status within the MRD window and recurrence-free survival (RFS) was assessed using Cox regression analysis. Additionally, any time postsurgical ctDNA positivity across serial time points and RFS was assessed using the Kaplan-Meier method.

Results: In total, 277 patients with Stage I-III resectable NSCLC and available clinical data were identified with a median age of 69 years at the time of surgery. A preliminary analysis was performed on 73 patients with a median follow-up of 3.3 years (range 1.6-7 years) and a median of 7 tests were performed per patient. Detection of ctDNA during the MRD window was associated with significantly worse RFS (HR: 20, 95% CI: 1.8-230, p=0.00061) compared to patients with non-detectable ctDNA. Additionally, among ctDNA-positive patients during the MRD window, those who received adjuvant therapy benefitted, reaching non-detectable ctDNA levels and remaining recurrence-free, compared to patients who did not receive adjuvant therapy. Conversely, ctDNA-negative patients showed no benefit of adjuvant therapy with no significant RFS change observed. Overall, 100% of ctDNA-positive patients at any time post-definitive therapy developed clinically confirmed recurrences. Notably, with serial testing, the assay demonstrated 100% specificity and positive predictive value (PPV), with a negative predictive value (NPV) of 100% for extra-cranial recurrences. Of the two patients with brain-only recurrences, one had detectable ctDNA prior to recurrence. The lead time analysis revealed ctDNA detection to precede any radiological recurrence by a median of 6.5 months (range: 1.3-12.3 months).

Conclusions: These findings demonstrate the value of the WGS-based ctDNA assay for identifying MRD and predicting relapse and adjuvant chemotherapy benefit in patients with early-stage resectable NSCLC. The high specificity and PPV highlight its potential utility in post-surgical risk stratification and individualized patient care. Full cohort analysis will be presented at the time of presentation.

Introduction: Savolitinib is a potent, highly selective and CNS-penetrant oral MET-tyrosine kinase inhibitor. In the Phase II SAVANNAH study (NCT03778229), osimertinib + savolitinib had a high rate of durable responses in patients with EGFR-mutated (EGFRm) advanced NSCLC and high tumour MET overexpression (OverExp) and/or amplification (Amp) after disease progression on osimertinib. We report exploratory analyses of concordance between next-generation sequencing (NGS) of tissue and of circulating tumour DNA (ctDNA) versus fluorescent in-situ hybridisation (FISH) ± immunohistochemistry (IHC) in detecting MET Amp ± OverExp. Plasma analyses for acquired resistance mechanisms to savolitinib ± osimertinib were reported.

Methods: Patients with EGFRm advanced NSCLC and MET OverExp and/or Amp after disease progression on osimertinib received osimertinib 80mg QD + savolitinib 300mg QD, 300mg BID or 600mg QD or savolitinib 300mg BID + placebo. MET OverExp /Amp was centrally confirmed (IHC [Roche], 3+ intensity in ≥50% of tumour cells [MET IHC3+/≥50%]; FISH [Abbott Molecular], ≥5 MET gene copies or MET:CEP7 ratio ≥2 [FISH5+]) or at higher thresholds (MET IHC3+/≥90% [IHC90+] or FISH10+) using tissue obtained following progression on prior osimertinib. Concordance between MET Amp by baseline tissue NGS (FoundationOne® CDx) or baseline ctDNA NGS (GuardantOMNI®) versus FISH ± IHC was assessed. Baseline ctDNA content was estimated using EGFRm (Ex19del/L858R) ctDNA. Paired plasma samples collected at baseline and treatment discontinuation (TD) were analysed using ctDNA NGS to identify acquired resistance mutations. The association of baseline EGFRm ctDNA with PFS was analyzed. DCO: 23 Aug 2024.

Results: Of 343 patients with valid NGS ctDNA data at baseline, 229 had high MET (IHC90+ and/or FISH10+) and 114 did not. Overall, 296/343 (86%) patients had detected EGFRm ctDNA at baseline; of these, 208/296 (70%) and 88/296 (30%) did and did not have high MET, respectively. Among patients with high MET treated with osimertinib + savolitinib, median PFS (mPFS) was numerically longer in patients with baseline undetected EGFRm ctDNA than detected EGFRm ctDNA (mPFS, months [95% CI]: 10.4 [5.3, 16.5] versus 5.7 [4.5, 7.4]). Comparison of MET ctDNA NGS to MET FISH showed modest positive-percent agreement (PPA, sensitivity; 47%) but high negative-percent agreement (NPA, specificity; 86%). Comparison of MET tissue NGS (n=70) to MET FISH showed high PPA (95%) and NPA (86%). When MET IHC90+ and/or FISH10+ were considered, PPA for both ctDNA and tissue NGS decreased to 36% and 62%, respectively, while maintaining high specificity (89% and 96%, respectively). In 105 patients with PFS ≥2 months and paired baseline and TD NGS ctDNA, the most commonly acquired events at TD associated with resistance mechanisms were in EGFR (13%), BRAF (11%), MET (10%), RAS (8%) and ERRB2/ERBB3 (5%).

Conclusions: Baseline detected EGFRm ctDNA was associated with high MET status (MET IHC90+ and/or FISH10+) and numerically shorter PFS on osimertinib + savolitinib vs undetected EGFRm, suggestive of a negative prognostic subgroup. MET ctDNA NGS had high specificity but modest sensitivity for MET FISH10+ detection, with further reduced sensitivity when IHC90+ was also considered. Acquired resistance mutation profiles to savolitinib ± osimertinib included known on-target and suspected bypass signalling resistance mechanisms.

MA03 NEW ADVANCES IN CIRCULATING BIOMARKERS
SUNDAY, SEPTEMBER 7, 2025 - 15:15 - 16:30

MA03.04 Comparative Analysis of Circulating Tumor DNA Monitoring Strategies in Advanced NSCLC With MET Exon 14 Skipping Treated With Ensartinib

Y. Xia[1], M. Zhou[1], J. Zhao[2], X. Sun[3], X. Le[4]
[1]Second Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou City, Zhejiang Province/CN ,[2]Second Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou/CN ,[3]First Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou/CN ,[4]University of Texas MD Anderson Cancer Center, Houston/TX/USA

Introduction: Circulating tumor DNA (ctDNA) has emerged as a promising tool for therapeutic monitoring. We have previously reported the main findings of the EMBRACE trial, based on which we further conducted a translational biomarker study.

Methods: Plasma samples were collected at baseline (V0), week 4 of treatment (V1), and at end of treatment (EOT). ctDNA was analyzed using a hybrid-capture NGS panel and categorized by three strategies: METex14 mutation only, Class I/II driver mutations, and all detectable mutations. ctDNA dynamics were correlated with objective response rate (ORR), progression-free survival (PFS), and overall survival (OS).

Results: Among 30 evaluable patients, baseline ctDNA positivity varied by definition: 48.3% for METex14, 48.3% for Class I/II mutations, and 75.9% for all mutations. Early ctDNA clearance at V1 predicted superior outcomes across strategies. METex14 clearance at V1 was associated with ORR of 80% vs 20% ($p = 0.03$) and mPFS of 9.33 vs 2.23 months ($p < 0.001$). Similar trends were observed for Class I/II and pan-mutation monitoring, although specificity declined with broader mutation inclusion. Persistent or re-emergent ctDNA positivity correlated with shorter survival. Longitudinal ctDNA positivity (>=2 positive timepoints) was a strong predictor of early progression. Notably, ctDNA dynamics preceded radiologic progression by a median of 1.61 months using METex14 or Class I/II monitoring, and up to 5.04 months with pan-mutation analysis, highlighting the trade-off between specificity and early molecular relapse detection. Multivariate analysis confirmed V1 ctDNA status as an independent prognostic factor for PFS.

Conclusions: This is the first study to prospectively compare mutation-specific ctDNA monitoring strategies in METex14 NSCLC. METex14 ctDNA clearance offers the highest specificity for treatment response, while broader mutation panels improve sensitivity for molecular progression. Our findings support the integration of early and longitudinal ctDNA dynamics into personalized monitoring and therapeutic decision-making for MET-targeted therapy.

MA03.05 Circulating Tumor DNA Tumor Fraction as a Precision Biomarker for Radiotherapy in Oligometastatic NSCLC

K. Parikh[1], N.P. Semenkovich[2], A. Hashmi[1], P. Chauhan[1], R. Ben-Shachar[4], A.S. Mansfield[1], S.S. Park[1], K. Olivier[1], D. Owen[1], A.A. Chaudhuri[1]
[1]Mayo Clinic, Rochester/MN/USA ,[2]Medical College of Wisconsin, Milwaukee/WI/USA ,[4]Tempus AI Inc., Chicago/IL/USA

Introduction: Local treatments are routinely used in addition to systemic therapy for treatment of oligometastatic lung cancers. However, there are significant challenges in identifying patients with oligometastatic NSCLC that are likely to benefit from local consolidative radiotherapy. Negative results from NRG-LU002 further highlight limitations in accurate patient identification. Our prior work demonstrated that higher pre-radiotherapy (RT) circulating tumor DNA (ctDNA) maximum variant allele fraction (VAF) was associated with worse OS (HR 5.7, p=0.004) and PFS (HR 4.7, p=0.02) in multivariate Cox regression analysis. Here we hypothesize that applying a multimodal algorithm-based cell-free DNA analytic approach (ctDNA-derived tumor fraction estimation or CTFE) to determine pre-RT ctDNA tumor fraction (ctDNA TF) can more robustly stratify patients who stand to benefit from consolidative RT for oligometastatic NSCLC.

Methods: Patients with oligometastatic NSCLC (metastasis in 1-5 organ systems) who underwent liquid biopsy ctDNA analysis using the 105-gene, hybrid-capture, NGS-based Tempus xF assay at any time prior to receiving RT were included in this study. ctDNA TF was estimated (CTFE) using an ensemble algorithm that incorporates pathogenic variant allele frequencies, copy number information, and germline information from plasma cell-free DNA. Limit of blank (LOB) was determined using 20 healthy subjects using the classical non-parametric rank-based approach. Overall survival (OS) and progression-free survival (PFS) were calculated from time of RT to minimize guarantee-time bias.

Results: Out of a real-world cohort of 1,487 patients with oligometastatic NSCLC, 309 patients who underwent RT were included in the final analysis. Median and mean ctDNA TF were 0.007 and 0.053, (range 0-0.522), respectively. Using LOB TF (0.0009) to determine ctDNA TF detectable versus undetectable, 221 patients were ctDNA TF detectable and 88 patients were ctDNA TF undetectable prior to RT. Median OS from time of RT was 25 months for ctDNA TF undetectable compared to 16.8 for ctDNA TF detectable patients (p=0.007). Median PFS was 8.7 months for ctDNA TF undetectable versus 5.2 months for ctDNA TF detectable patients (p=0.01). In multivariate Cox proportional hazards regression analysis, we observed that age, histology, and gender were not associated with OS or PFS. However, ctDNA TF was independently associated with worse OS (HR 23.0, 95% CI 4.038-109.0, p=0.0002) and worse PFS (HR 45.2, 95% CI 7.776-218.4, p<0.0001).

Conclusions: In oligometastatic NSCLC, pre-RT liquid biopsy-based ctDNA TF is a stronger predictor of survival (HR 23.0) than ctDNA maximum VAF (HR 5.7) and can be successfully utilized to risk-stratify patients who are likely to benefit from consolidative RT. Lack of ctDNA detection prior to RT based on CTFE analysis, likely reflective of minimal micrometastatic disease burden, was associated with significantly improved PFS and OS in patients who underwent RT.

MA03.06 Intrathecal Pemetrexed for Lung Adenocarcinoma Leptomeningeal Metastasis: A Study on Efficacy and Liquid Proteomics

Z. Wang, P. Ding, F. Tong, X. Dong
Cancer Center, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan/CN

Introduction: Leptomeningeal metastasis (LM), a devastating neurological complication of advanced lung adenocarcinoma (LUAD). The therapeutic potential of intrathecal pemetrexed (IP) and associated biomarkers remains unexplored. Therefore, we investigated the efficacy of IP and identified biomarkers through proteomic profiling of cerebrospinal fluid (CSF) and plasma samples.

Methods: This study enrolled LUAD patients with LM. Following 1:1 propensity score matching (PSM) patients were stratified into IP and non-IP cohorts. IP patients were divided into responders (R) who achieved partial response (PR) and nonresponders (NR) who with stable disease (SD) and progressive disease (PD). Paired baseline plasma and CSF proteomic profiling was performed using Olink Immuno-Oncology panels. Differential expression protein (DEP) analysis was conducted between two cohorts.

Results: The analysis included 163 LM patients, 82 balanced pairs were established in each matched cohort. Multivariable Cox regression revealed that IP reduced mortality risk (HR = 0.427, p = 0.022) and Eastern Cooperative Oncology Group (ECOG) 3-4 conferred higher mortality (HR = 2.737, p = 0.005). The survival benefit of IP was particularly demonstrated in ECOG 3-4 subgroup with median overall survival 11.2 vs 2.5 months (IP vs non-IP, log-rank p = 0.0029). In the Olink proteomic analysis of 18 patients (8 responders (PR) vs 10 nonresponders (SD=8, PD=2) showed that lower plasma MCP-2 and higher CSF ARG1 levels significantly distinguished the responders from the nonresponders (AUC=0.873 and 0.875, respectively).

Conclusions: IP treatment is an independent factor for improving survival in LUAD patients with LM, particularly as salvage therapy for ECOG 3-4 patients. IP treatment response may be predicted through CSF and plasma biomarkers identified via proteomic profiling.

MA03.07 Multi-Omic Analyses of CSF Reveal Genomic Instability and Suppressed Microenvironment After TKI Resistance in Patients With Brain Metastases

M. Li, M. Yu, Y. Pan, L. Chen
sun yat-sen university cancer center, Guangzhou/CN

Introduction: Patients with epidermal growth factor receptor (EGFR)-mutated non-small cell lung cancer (NSCLC) and brain metastases show notable response to tyrosine kinase inhibitors (TKI) treatment, and almost all patients eventually develop resistance. However, treatment options are limited after TKI resistance, and underlying resistance mechanism of approximately 50% patients remained unknown, especially for patients with brain metastases. Cerebrospinal fluid (CSF) can be used as a type of liquid biopsy to detect brain tumors. Here, we explore the dynamic changes of genetics and microenvironment before and after TKI resistance based on CSF in patients with brain metastases.

Methods: We performed circulating tumor DNA (ctDNA) 425-genes targeted sequencing and single-cell RNA sequencing from a total 164 CSF samples of patients with EGFR mutated NSCLC and brain metastases (51 samples on baseline and 113 samples on TKI resistance).

Results: The CSF ctDNA genomic profiling revealed higher levels of tumor mutation burden (TMB), intratumor heterogeneity (ITH), and copy number variants (CNVs) after TKI resistance, indicating a strong signal of genomic instability. Higher levels of TMB and ITH in resistance CSF were also associated with poor prognosis in patients with brain metastases. The patients with EGFR 21L858R or 3rd-generation TKIs resistance showed an increased incidence of undefined resistance mechanisms. CSF scRNA-seq showed that increased macrophages proportion and decreased T cells proportion after TKI resistance. The macrophages in resistance CSF displayed enhanced immunosuppressive and lipid metabolism phenotype. We defined a population of lipid-associated macrophages, named FABP5_M, was significantly increased after TKI resistance, which may regulated by endothelin-1 (EDN1) from malignant epithelial cells. A receptor-ligand interaction analysis revealed that FABP5_M may contribute to immunosuppressive microenvironment through interaction with exhausted T cell via LGALS9-HAVCR2 axis. Particularly, we found a population of cancer stem-like cells in CSF, which highly expressed CD44, HLDH1A1 and BMI1, may develop leptomeningeal metastases after TKI resistance.

Conclusions: We revealed a comprehensive understanding of genetic profiling and tumor microenvironment remodeling after TKI resistance based on CSF sequencing, and provided potential target strategy for patients with EGFR mutated NSCLC and brain metastases after TKI resistance.

MA03.08 Identification of Circulating microRNA Signature for Diagnosis and Prognosis of Checkpoint Inhibitor-Related Pneumonitis

H. Deng, Y. Yang, Y. Yang, F. Wang, X. Lin, L. Wang, C. Zhou
The First Affiliated Hospital of Guangzhou Medical University, Guangzhou Medical University,, Guangzhou/CN

Introduction: Checkpoint inhibitor-related pneumonitis (CIP) represents a highly lethal immune-related adverse event. The early diagnosis of CIP is crucial for timely intervention and improved prognosis; however, the absence of precise and effective diagnostic techniques often leads to its underdiagnosis and misdiagnosis. This study aims to identify microRNA (miRNA) features from serum and serum-derived extracellular vesicles (EVs) for the early detection and prognostic evaluation of CIP.

Methods: Small RNA sequencing was conducted to identify candidate miRNAs as potential diagnostic biomarkers in 27 serum-derived EV samples from patients with CIP (CIP group) and non-CIP patients, including those with lung cancer who received immunotherapy without developing CIP (ICI group) and patients with infectious pneumonia (PNE group). These miRNA candidates were screened in the discovery cohort (n=48) and further validated in serum and EV samples within a training cohort (n=106) and a validation cohort (n=72) using a quantitative reverse transcription-polymerase chain reaction (qRT-PCR) and a logistic regression model to establish and validate the diagnostic signature. Using a Cox regression model, we built a prognostic risk stratification for CIP patients based on three miRNAs.

Results: The sequencing analysis initially screened and identified a panel of 13 overexpressed miRNAs in patients with CIP. Subsequently, qRT-PCR demonstrated that three specific miRNAs (EVs miR-193a-5p, serum miR-193a-5p, and serum miR-378a-3p), effectively distinguished CIP patients from non-CIP individuals [training cohort: AUC=0.870, 95% confidence interval (CI), 0.778-0.962; validation cohort: AUC=0.837, 95%CI, 0.712-0.962). Notably, this miRNA signature was equally robust in differentiating CIP from the ICI group (training cohort: AUC=0.823, 95%CI: 0.695-0.950; validation cohort: AUC=0.845, 95%CI: 0.710-0.979) and the PNE group (training cohort: AUC=0.892, 95%CI: 0.794-0.989; validation cohort: AUC=0.907, 95%CI: 0.810-1.000). Furthermore, when combined with lymphocyte levels, the miRNA signature significantly enhanced the overall diagnostic accuracy in distinguishing CIP from non-CIP patients (training cohort: AUC=0.900, 95%CI: 0.808-0.993; validation cohort: AUC=0.932, 95%CI: 0.865-1.000), and maintained its robustness in distinguishing CIP from the ICI group (training cohort: AUC=0.898, 95%CI: 0.798-0.998; validation cohort: AUC=0.946, 95%CI: 0.880-1.000) and the PNE group (training cohort: AUC=0.938, 95%CI: 0.858-1.000; validation cohort: AUC=0.959, 95%CI: 0.899-1.000). Additionally, the three-miRNA panel was independently and significantly associated with overall survival in CIP patients (hazard ratio: 2.827; 95% CI, 1.051-7·603; p=0.040).

Conclusions: Our circulating miRNA-based signature represents a noninvasive and robust diagnostic tool for CIP patients, and could accurately predict their prognosis. This signature may facilitate early detection and personalized management of these patients.

MA03.09 Minimal Residual Disease Dynamic Monitoring in First-Line Serplulimab Plus Chemotherapy in Treatment of Extensive-Stage Small Cell Lung Cancer

K. Ma[1], X. Chen[1], Y. Xu[1], X. Wang[1], C. Sun[1], S. Qiu[1]
[1]First Hospital of Jilin University, Changchun/CN

Introduction: Extensive-stage small cell lung cancer (ES-SCLC) is an aggressive type of lung cancer exhibiting rapid growth with a poor prognosis, and although etoposide plus platinum-based chemotherapy in combination with PD-1/PD-L1 inhibitors (e.g., Serplulimab) has significantly prolonged survival, there is still significant heterogeneity in the depth and duration of patients' remission. Minimal residual disease (MRD), detected by circulating tumor DNA (ctDNA), dynamically reflects residual tumor load after treatment and has gradually become a biomarker for predicting recurrence and survival in solid tumors. However, its value in ES-SCLC, especially its dynamic evolution pattern in chemo-immunotherapy modality and its association with long-term prognosis is unclear. Our prospective study(NCT05873790) aims to longitudinally monitor MRD dynamics to evaluate treatment efficacy in ES-SCLC.

Methods: This study prospectively enrolled previously untreated ES-SCLC patients. All patients received 6 cycles of standard chemotherapy combined with serplulimab, followed by serplulimab monotherapy maintenance. Plasma ctDNA samples were collected at multiple time points, including the baseline, after 2 and 6 cycles of chemo-immunotherapy, at 6 months post-chemotherapy cessation, and upon tumor progression. The MRD status was identified by a next-generation sequencing panel covering 2365 lung cancer-relevant genes with an average sequencing depth of approximately 30000×. Kaplan-Meier curves and log-rank tests were performed in survival analyses.

Results: A total of 13 eligible patients were consecutively enrolled between November 2023 and December 2024. At the data cutoff, the median progression-free survival (PFS) was 6.67 months. MRD positivity was observed in all baseline samples, and the positivity rate decreased dramatically to 54% after 2 cycles of chemo-immunotherapy (p=0.003).Patients with MRD negativity after 2 treatment cycles had significantly prolonged PFS compared to MRD-positive patients (7.23 vs. 5.97 months, P=0.031). Among patients with MRD conversion to negativity during treatment, PFS was not reached, while those with persistent MRD positivity had a median PFS of 6.45 months (P=0.043). Most patients exhibited MRD conversion to positivity or increased ctDNA levels at tumor progression. Three patients showed re-elevation of ctDNA levels post-treatment, with radiographic progression confirmed 2.27, 1.7, and 1.6 months later, respectively. These findings indicate that patients with residual MRD positivity post-treatment harbor a higher risk of progression, and MRD status may precede radiographic detection of tumor progression.

Conclusions: This is the first prospective study to evaluate ctDNA-MRD systematically in ES-SCLC patients receiving chemo-immunotherapy. ctDNA-derived MRD can identify ES-SCLC with a high disease progression risk through longitudinal monitoring.

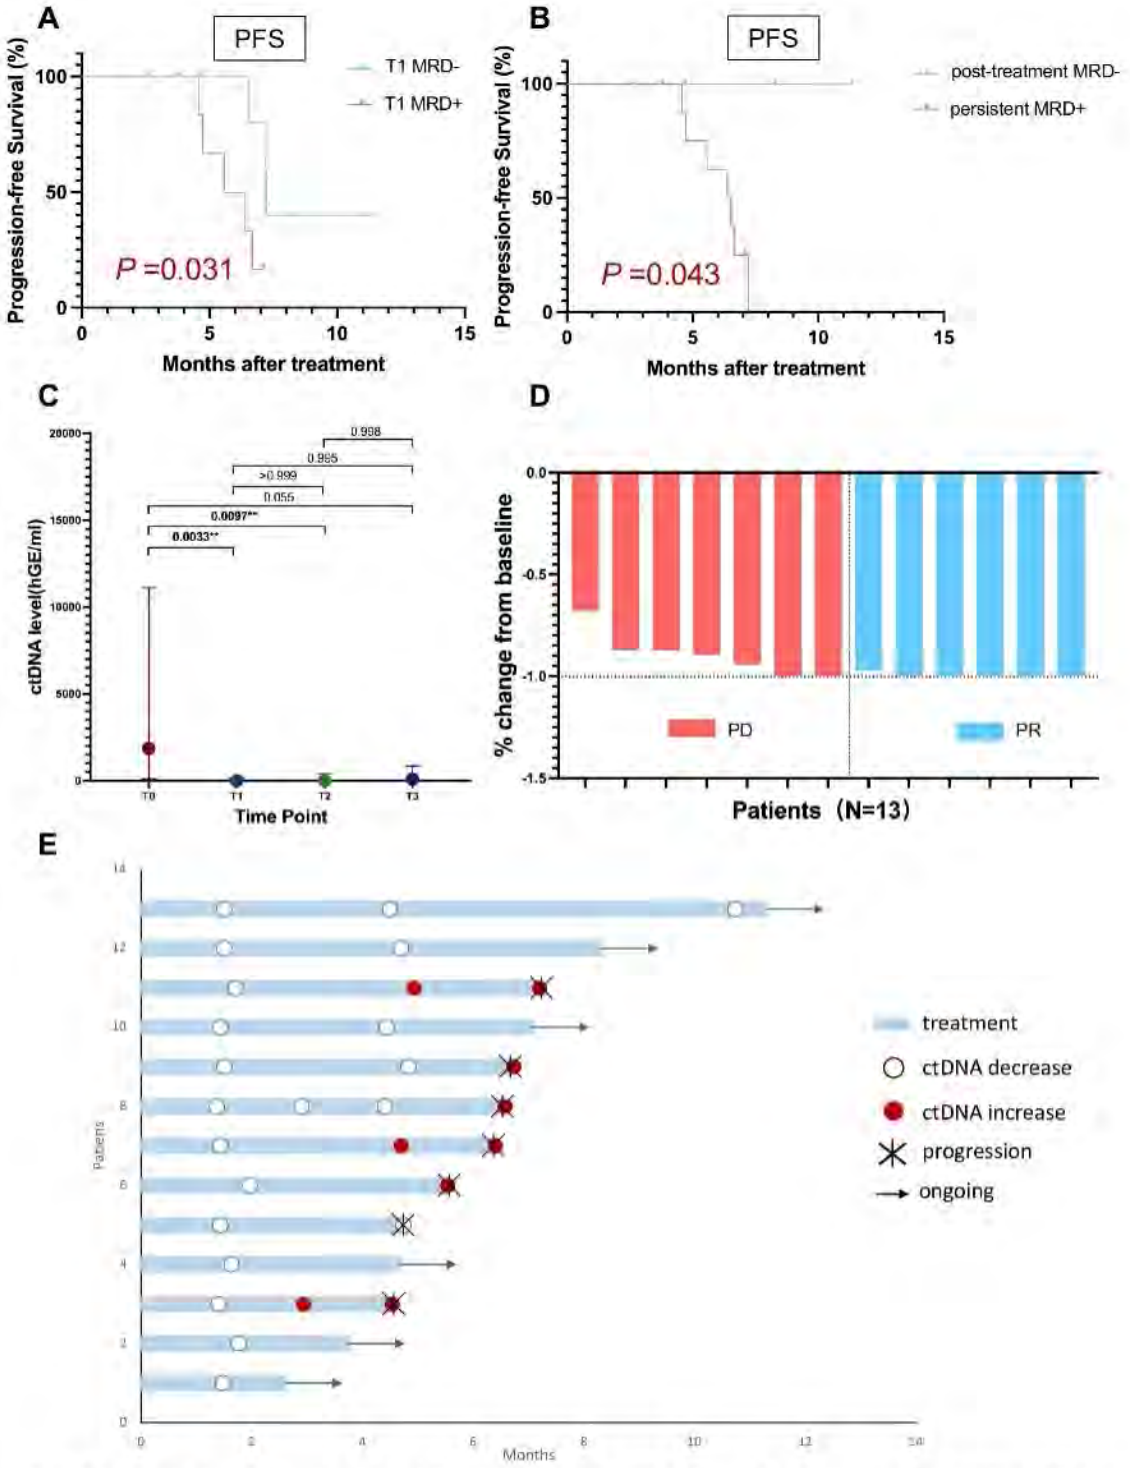

Fig.1 Longitudinal assessment of MRD dynamics and clinical outcomes. **A,** Kaplan–Meier curves comparing progression-free survival (PFS) between MRD-positive and MRD-negative patients after 2 cycles of treatment. **B**, Kaplan–Meier analysis of PFS in patients with persistent MRD positivity versus those achieving MRD clearance during treatment. **C**, Longitudinal changes in ctDNA levels across predefined timepoints: baseline (T0), post-cycle 2 (T1) and 6 (T2), 6 months post-chemotherapy cessation (T3), and tumor progression. **D**, Percentage reduction in ctDNA levels from baseline after treatment. **E**, Swimmer plot illustrating MRD trajectory and treatment response for all enrolled patients.

MA04.01 No Versus Systematic Mediastinal LN Dissection for GGO-Dominant Lung Adenocarcinoma: A Multicenter, Phase III, Non-Inferiority RCT

Y. Zhang, H. Chen
Fudan University Shanghai Cancer Center, Shanghai/CN

Introduction: Systematic mediastinal lymph node dissection (LND) or sampling is currently recommended for patients with early-stage non-small cell lung cancer (NSCLC). However, the potential harm resulting from removing non-metastatic LN remains under-recognized.

Methods: We conducted a multicenter, open-label, phase III, non-inferiority randomized controlled trial comparing systematic mediastinal LND versus no mediastinal LND in patients with ground glass opacity (GGO)-dominant invasive lung adenocarcinoma, who were predicted to have no LN metastasis based on criteria established in our prior trial. The primary endpoint was 3-year disease-free survival. An interim analysis was planned upon enrollment of 300 patients, with predefined termination criteria if no mediastinal LN metastasis is detected and life-threatening complications occur in the systematic LND arm. This trial is registered on ClinicalTrials.gov (ECTOP-1009, NCT04527419).

Results: Interim analysis of 302 patients revealed no LN metastasis in either study arm. The no LND group had significantly reduced surgery duration (mean: 73 min vs. 109 min, P<0.001), blood loss (mean: 45 ml vs. 89 ml, P<0.001), and postoperative hospital stay (mean: 3.7 days vs. 4.4 days, P=0.002). Complications observed in the systematic LND group included arrhythmia in three patients (2.0%), chylothorax in one patient (0.7%), and one case (0.7%) of intraoperative massive bleeding due to superior vena cava injury. No lymphadenectomy-related complications occurred in the no LND group.

Conclusions: Based on interim findings and the principle of non-maleficence, the trial should be terminated. Systematic mediastinal LND should no longer be recommended for patients with GGO-dominant lung adenocarcinoma.$$graphic_{89D1A54C-228E-4D34-ABFC-75D5EA23C5EC}$$$$graphic_{2AD4A8BD-CFF9-4BC8-8D4C-20C1D636616A}$$

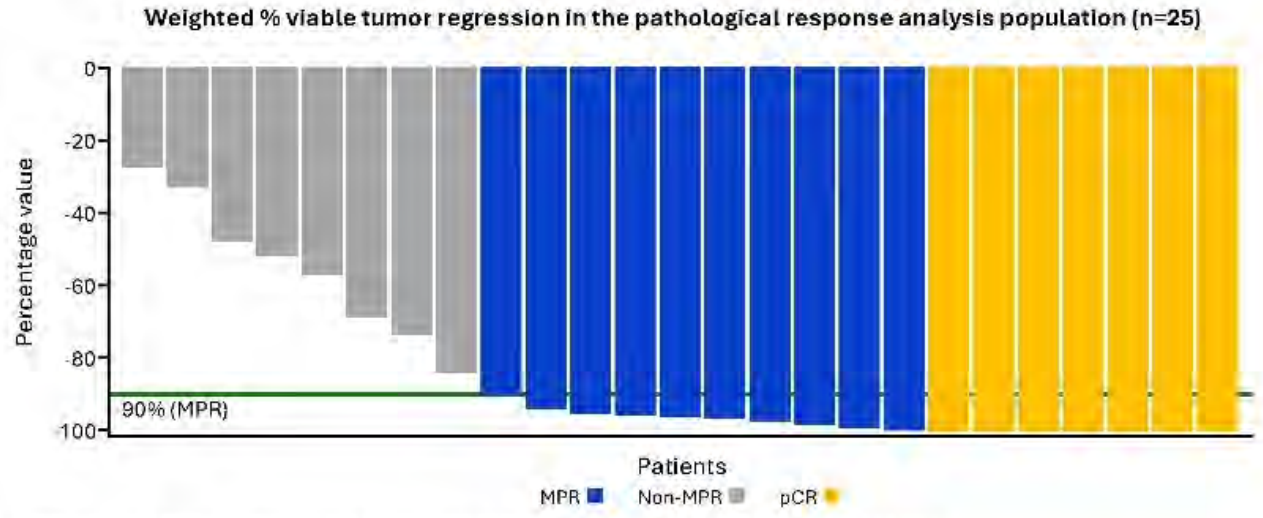
Introduction: Alectinib is globally approved in the adjuvant setting for patients with resected, anaplastic lymphoma kinase-positive (ALK+), stage IB–IIIB (AJCC 8th edition) non-small cell lung cancer (NSCLC). There is a need for exploring targeted therapies in the neoadjuvant setting in this population. NAUTIKA1 (NCT04302025) is a phase II umbrella study investigating targeted treatments in the neoadjuvant/adjuvant setting in early-stage NSCLC with study-eligible alterations (e.g., ALK, ROS1, NTRK and KRAS G12C). Preliminary data from 12 patients in the ALK+ cohort were previously presented. We present new clinical and surgical outcomes from 33 patients in this cohort.

Methods: Eligible patients were ≥18 years old with stage IB, II, IIIA or selected IIIB (T3N2 only) ALK+ NSCLC, and ECOG PS 0/1. Patients received neoadjuvant alectinib (600mg, twice-daily [BID]) for eight weeks followed by surgery, platinum-based chemotherapy (≤4 cycles) unless refused, not indicated or contraindicated, then adjuvant alectinib (600mg BID) for two years. Primary endpoint was locally assessed major pathological response (MPR; ≤10% residual viable tumor cells). Secondary endpoints included pathological complete response (pCR), radiographic response, nodal downstaging and safety.

Results: At data cutoff (02 September 2024), 33 patients were enrolled; see Table for baseline characteristics. Primary endpoint of MPR was achieved in 17/28 (60.7%) patients, and pCR in 7/28 (25.0%) (Figure). Radiographic objective response was observed in 19/30 patients (63.3%), and nodal downstaging in 8/30 (26.7%). No intraoperative complications occurred. In patients who underwent surgery, 25/27 (92.6%) had R0 resections; see Table for surgical outcomes. Adverse events led to dose reduction/interruption or discontinuation in 12/33 (36.4%) and 3/33 (9.1%) patients, respectively. Neoadjuvant alectinib was well tolerated with no new safety signals.

Conclusions: Neoadjuvant alectinib achieved clinically meaningful MPR/pCR rates with no new safety signals, and can be added to ALINA as a promising perioperative approach for patients with resectable, stage IB-IIIB ALK+ NSCLC.



MPR, major pathological response (primary endpoint); pCR, pathological complete response.

Weighted % viable tumor regression values were set to 'missing' for patients who did not undergo primary tumor R0 resection.

Data cutoff date 02 September 2024, for patients enrolled on or before 28 May 2024. [1]Per protocol, patients were to be treated until the day before surgery. [2]Assessed in eligible and treated patients. [3]Pathological response was assessed locally; pathological response analysis population defined as all eligible and treated patients who either underwent post-neoadjuvant surgery (with or without resection; n=27) or discontinued due to AE or disease progression (n=1 due to PD) with pathological response for patients without R0 resection set to non-MPR. [4]Defined as the lack of any viable tumor cells on review of hematoxylin and eosin stained slides, determined by local pathologist after complete evaluation of a resected lung cancer specimen including all sampled regional lymph nodes. [5]Eligible and treated patients who underwent post-neoadjuvant surgery (with or without resection). [6]Surgery was considered to be delayed if performed after Day 57 on study. [7]One patient had pneumonitis after completion of neoadjuvant treatment which led to the physician decision for patient to not receive adjuvant treatment. [8]One patient did not proceed with resection due to surgeon decision as the patient required a pneumonectomy; second patient did not proceed with resection due to pleural disease (indicating metastatic disease) found at the time of surgery. [9]Left upper lobectomy, mediastinoscopy.

Introduction: Pathological subtypes are prognostic indicators independent of TNM stage. Patients (pts) with high risk (solid, micropapillary, or complex gland) had poorer prognosis. APPOINT (NCT04922138) is the first two-arm study to explore the efficacy and safety of the third-generation epidermal growth factor receptor-tyrosine kinase inhibitors (EGFR-TKI) aumolertinib as adjuvant therapy in stage I A EGFR mutated NSCLC pts with high risk factors. Previously, we reported 1-year disease free survival (DFS) rate (ELCC 2025 145P), here, we update the primary endpoint data.

Methods: This prospective, multi-center, two-arm study aims to enroll 102 stage I A EGFR-mutated NSCLC pts with solid, micropapillary, and/or complex gland components ≥10%. After radical lung cancer surgery, they will receive oral aumolertinib 110 mg qd as adjuvant therapy (arm A) or observation (arm B) for 3 years. The primary endpoint is 2-year DFS rate, and secondary endpoints include 3-, 4-, and 5-year DFS rate, 5-year overall survival rate and safety.

Results: At data cut off, a total of 97 stage I A EGFRmutated (19Del, L858R and uncommon mutations) NSCLC pts were enrolled with at least one high-risk factors, including solid, micropapillary, and/or complex gland components. 46 in arm A and 51 in arm B. The median age was 57 and 66 years, 62.2 % and 62.7% were female, respectively. At data cut-off, the median follow up time was 20 months, all pts in arm A had no symptoms of tumor recurrence and 4 pts in arm B had recurrence, the special disease of 2-year DFS was 100% vs 75% (p=0.033). There were no grade ≥3 AE occurred during aumolertinib treatment group, and no new safety signals were observed.

Conclusions: The data demonstrated that compared with the observation group, aumolertinib treatment group exhibited superior efficacy and safety in stage IA EGFR mutated NSCLC pts with high-risk pathological features, highlighting its clinical utility potential for EGFR mutated stage IA NSCLC management.

MA04.04 Perioperative Pembrolizumab in Non-Small Cell Cancer (NSCLC): 4-Year Outcomes by Nodal Status in the KEYNOTE-671 Study

H. Wakelee[1], I. Demedts[2], A. Langleben[3], X. Yan[4], M. Faehling[5], G. Lo Russo[6], J-Y. Han[7], E. Levchenko[8], G. Ursol[9], E. Cronemberger[10], S. Wang[11], B. Zurawski[12], O. Voitko[13], E. Jensen[14], S.M. Keller[14], A. Samkari[14], D.R. Jones[15]

Introduction: In the phase 3 KEYNOTE-671 study (NCT03425643), neoadjuvant pembrolizumab plus chemotherapy followed by surgery and adjuvant pembrolizumab significantly improved event-free survival (EFS), overall survival (OS), major pathological response (MPR), and pathological complete response (pCR) versus neoadjuvant chemotherapy and surgery alone. In this exploratory analysis, we report outcomes by baseline clinical nodal status in participants from KEYNOTE-671.

Methods: Participants aged ≥18 years with previously untreated resectable stage II, IIIA, or IIIB (N2) NSCLC were randomized to pembrolizumab 200 mg or placebo plus chemotherapy Q3W for 4 cycles, then surgery and adjuvant pembrolizumab or placebo for ≤13 cycles (~9 months). Exploratory analyses of EFS, OS, MPR, and pCR were performed in subgroups of participants with clinically node-negative (cN0) and node-positive (cN1/cN2) disease at baseline.

Results: Of 797 participants enrolled in KEYNOTE-671, 290 participants had cN0 disease (n = 148 randomized to pembrolizumab and n = 142 to placebo) and 506 participants had cN1/cN2 disease (n = 248 randomized to pembrolizumab and n = 258 to placebo) at baseline. Median follow-up time as of the data cutoff (August 19, 2024) was 41.1 (range, 0.4-75.3) months. Among participants who underwent surgery, 108/117 (92.3%) in the pembrolizumab arm and 98/115 (85.2%) in the placebo arm of the cN0 subgroup and 190/207 (91.8%) and 169/202 (83.7%), respectively, in the cN1/cN2 subgroup had R0 resections. EFS, OS, MPR, and pCR favored pembrolizumab versus placebo irrespective of nodal status (Table). Outcomes by disease stage within each nodal subgroup will also be presented. Grade 3 to 5 treatment-related AEs occurred in 68/147 participants (46.3%) in the pembrolizumab arm and 55/142 participants (38.7%) in the placebo arm in the cN0 subgroup and in 111/248 participants (44.8%) and 96/257 participants (37.4%), respectively, in the cN1/cN2 subgroup.

Conclusions: In this exploratory analysis, perioperative pembrolizumab improved efficacy outcomes versus neoadjuvant chemotherapy alone regardless of nodal status after ~4 years of follow-up in participants with stage II to IIIB (N2) NSCLC.

Introduction: Immune checkpoint inhibitors (ICI) can lead to a major pathological response (MPR) in a subset of patients, but the immunological drivers of response remain elusive. This study is a secondary analysis of the prospective, phase II NEOMUN trial, leveraging multi-omics data to characterize the tumor microenvironment (TME) after mono-immunotherapy with Pembrolizumab from a controlled clinical setting. We hypothesized that distinct immunological functions would contribute to efficacy of Pembrolizumab, and that therefore changes in the TME would be detectable in tumors with MPR as compared to non-responders or untreated controls.

Methods: In the NEOMUN trial, 29 patients were treated with neoadjuvant mono-immunotherapy with Pembrolizumab. 7 patients showed MPR with less than 10% vital tumor cells in resected specimen, all others were classified as non-MPR. Treatment-naïve controls were matched to the study cohort. Transcriptomics analysis and cytokine/chemokine measurements were performed to investigate functionality of the TME.

Results: Subpopulations of tumor-infiltrating leukocytes (TILs) were investigated based on a deconvolution approach using the tools CIBERSORT and xCell, revealing significant differences of TME composition in the MPR group compared to non-MPR and untreated controls. In particular, the infiltration of specific TIL subpopulations related to adaptive immunity was associated with MPR including B cells ($p<0.01$), CD8+ T cells ($p<0.001$), follicular helper T cells ($p<0.05$) and gamma-delta T cells ($p<0.001$). Interestingly, the TME composition of tumors in the non-MPR group resembled that of untreated controls, both regarding infiltration levels of specific TIL subpopulations associated with MPR and overall immune scores and stromal scores. Functional and network analysis of differentially expressed genes demonstrated a significant upregulation of T cell receptor signaling, B cell differentiation, B cell proliferation, B cell activation, B cell receptor signaling pathway and complement activation in the MPR group based on gene ontology (GO) enrichment analysis and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis. To validate how transcriptional changes correspond to actual functional immune signaling, we proceeded to conduct a proteomic analysis measuring a panel of 50 cytokines and chemokines. We observed a significant elevation of cytokines in the MPR group including CCL3, CCL4, CCL5, IL9, IL16, TNF-β and G-CSF, suggesting a complex immune activation signature involving both innate and adaptive immune activation with T Cell recruitment and activation, as well as NK cell and monocyte involvement.

Conclusions: In this deep exploratory analysis, several distinct mechanisms associated with major pathologic response were demonstrated. While confirming activation of CD8+ T cells as a key mechanism of action, B cell immunity might also play a substantial role for Pembrolizumab efficacy. Further studies are needed to determine if characterization of the TME and functionality of the involved pathways could be performed on preoperative tissue biopsy to predict therapy response.

Introduction: Neoadjuvant chemotherapy plus immunotherapy with adjuvant immunotherapy is the current standard of care for resectable NSCLC. There is an unmet need for additional neoadjuvant regimens containing novel agents that retain efficacy but minimize safety risks. We report results from a phase 2, randomized, open-label, multicenter umbrella trial of neoadjuvant tislelizumab (TIS) monotherapy and TIS-based immunotherapy combinations ± chemotherapy in Chinese patients with resectable NSCLC (NCT05577702).

Methods: Eligible patients had Stage II-IIIA NSCLC without EGFR sensitizing mutations or ALK rearrangement. Patients with PD-L1 TC ≥50% were assigned to Substudy 1 and randomized to TIS (anti-PD-1; Arm 1A), TIS plus ociperlimab (anti-TIGIT; Arm 1B), or TIS plus LBL-007 (anti-LAG-3; Arm 1C); patients with PD-L1 TC <50% were assigned to Substudy 2 and randomized to TIS and chemotherapy (Arm 2A) or TIS plus LBL-007 and chemotherapy (Arm 2C). Patients received 2-4 cycles of treatment and then surgery. The primary objective was evaluation of major pathological response (MPR) per blinded independent pathology review (BIPR); select secondary objectives were evaluation of the pathological complete response (pCR) per BIPR and feasibility of surgery.

Results: As of February 5, 2025, 121 patients were enrolled. The median number of treatment cycles of TIS or TIS-based immunotherapy combinations was 3, 2, and 2 for 1A, 1B and 1C, and 3 and 2.5 for 2A and 2C, respectively. The overall MPR rates were 64.3% (27/42) for Substudy 1, and 52.1% (25/48) for Substudy 2. Detailed MPR and pCR rates are summarized in the Table. Notably, in the experimental arms, the MPR rate in patients with non-squamous NSCLC in 1B was 100% (6/6) and in patients with squamous NSCLC with PD-L1 TC <1% in 2C was 75% (9/12). TEAEs were reported in most patients. The three most common treatment-related TEAEs were AST increased, anemia and ALT increased in Substudy 1, and neutrophil count decreased, anemia and WBC count decreased in Substudy 2. An increase in treatment-related Grade ≥3 and serious TEAEs, and immune-mediated AEs were reported for 1B and 1C versus 1A, and 2C versus 2A. Few treatment-related TEAEs leading to surgery withdrawal were reported.

Conclusions: Neoadjuvant TIS as monotherapy or TIS-based immunotherapy combinations in PD-L1 TC ≥50% NSCLC had promising MPR/pCR; the addition of other immunotherapy to neoadjuvant TIS and chemotherapy in PD-L1 TC <50% did not provide additional efficacy benefit. Treatment guided by histology and PD-L1 expression is suggested for future exploration.

Introduction: Interim analyses (IAs) from RATIONALE-315 demonstrated that perioperative tislelizumab plus neoadjuvant chemotherapy had clinically meaningful and statistically significant improvement in major pathological response (MPR), event-free survival (EFS), and pathological complete response (pCR), with a manageable safety/tolerability profile, compared with neoadjuvant chemotherapy in patients with resectable non-small cell lung cancer (NSCLC). We report results of the prespecified EFS/OS final analysis (FA).

Methods: Adults with untreated, resectable, stage II-IIIA NSCLC were randomised 1:1 to neoadjuvant tislelizumab 200 mg or placebo every 3 weeks plus platinum-based doublet chemotherapy for 3-4 cycles, followed by surgery and adjuvant tislelizumab 400 mg or placebo every 6 weeks for ≤8 cycles. As MPR, EFS, and pCR were statistically significant at IAs, only OS was statistically tested at FA.

Results: Overall, 453 patients were randomised (tislelizumab, n=226; placebo, n=227). Over 90% of patients completed neoadjuvant treatment (tislelizumab, n=211; placebo, n=210), 363 (80.1%) had surgery (tislelizumab, n=190; placebo, n=173), and 224 (49.4%) completed adjuvant treatment (tislelizumab, n=115; placebo, n=109). With a median study follow-up of 38.5 months (data cutoff: Mar 7, 2025), a statistically significant and clinically meaningful OS benefit was observed in the tislelizumab arm vs placebo arm (HR=0.65 [95% CI: 0.45, 0.93]; one-sided P=.0093). The significant EFS benefit reported with tislelizumab over placebo in the IAs was sustained (Figure 1; HR=0.58 [95% CI: 0.43, 0.79]), and improvement in EFS was consistent whether assessed by independent review committee (IRC) or the investigator. EFSIRC and OS benefits observed with tislelizumab were also observed across major subgroups, regardless of PD-L1 expression, disease stage, and histology type. Disease-free survival, assessed by IRC, was also improved with tislelizumab vs placebo in patients with complete resection. With the longer follow-up, safety/tolerability profiles were consistent with IAs, and no new or worsening signals emerged. Rates of grade ≥3 and serious TRAEs were 73.0% vs 67.3% and 15.5% vs 8.8% in the tislelizumab and placebo arms, respectively. The most frequently reported TRAEs of any grade were neutropenia (tislelizumab, 78.8%; placebo, 78.3%) and leukopenia (tislelizumab, 63.3%; placebo, 67.3%); these were also the most common grade ≥3 TRAEs in both arms (neutropenia: tislelizumab, 61.5%; placebo, 59.3%; leukopenia: tislelizumab, 16.8%; placebo, 14.2%). **Conclusions:** Neoadjuvant tislelizumab plus chemotherapy and adjuvant tislelizumab demonstrated statistically significant, clinically meaningful OS benefit and sustained significant EFS improvement compared with neoadjuvant chemotherapy in patients with resectable NSCLC, potentially offering a new treatment paradigm that is generally well tolerated and safe for this population.
CI, confidence interval; NE, not estimable; NR, not reached.

Introduction: In the phase 3 AEGEAN trial of patients with resectable NSCLC (R-NSCLC), perioperative durvalumab plus neoadjuvant chemotherapy significantly improved the primary endpoints of EFS and pathological complete response versus neoadjuvant chemotherapy alone. Here, we report patterns of progression and recurrence in AEGEAN.

Methods: AEGEAN is a double-blind, placebo-controlled study (NCT03800134) of patients with treatment-naïve R-NSCLC (stage II-IIIB[N2]) and ECOG PS 0/1. Patients were randomised (1:1) to neoadjuvant chemotherapy plus durvalumab or placebo IV (Q3W for 4 cycles) before surgery, followed by adjuvant durvalumab or placebo IV (Q4W, up to 12 cycles). Randomisation was stratified by stage and PD-L1 status. Efficacy was analysed in the modified intent-to-treat (mITT) population, which excluded patients with EGFR/ALK aberrations. EFS was defined as time from randomisation to PD precluding or preventing completion of surgery, recurrence, or death. PD precluding/preventing completion of surgery was based on clinical assessment by the investigator (among patients unable to undergo/complete surgery for reasons other than PD, it was assessed by BICR [RECIST v1.1]). Recurrence was assessed by BICR (RECIST v1.1) for patients after resection of the primary disease and included new NSCLC lesions, categorised as distant (including the pleura) or locoregional, but excluded new primary malignancies. The proportions of patients with progressions or recurrences were descriptively summarized.

Results: 802 patients were randomised (mITT, n=740); 799 received treatment (durvalumab arm, n=400; placebo arm, n=399). As of May 10, 2024, proportionally fewer patients in the durvalumab versus placebo arm had PD that precluded (7.7% vs 9.6%) or prevented completion of (1.4% vs 3.5%) surgery (Table); 0.8% and 2.7%, respectively, had PD after surgery was not undertaken/completed for reasons other than PD. Among patients who completed surgery, proportionally fewer in the durvalumab versus placebo arm had recurrences (14.5% vs 22.2%) (Table); median time to recurrence was longer in the durvalumab arm, irrespective of location, and proportionally fewer in the durvalumab arm had locoregional or distant only recurrences. Among patients who did not undergo/complete surgery, 39.0% in the durvalumab arm and 44.8% in the placebo arm received post-discontinuation therapy (Table); among patients who completed surgery, approximately twice as many in the placebo arm had subsequent therapy (13.7% vs 25.1%). **Conclusions:** The addition of perioperative durvalumab to neoadjuvant chemotherapy reduced PD precluding/preventing completion of surgery and both locoregional and distant post-surgery recurrences. In addition, time to recurrence was longer with perioperative durvalumab, providing further support for its use as a new treatment option.

Table

	Durvalumab arm (n=366)	Placebo arm (n=374)
Total EFS events, n (%)	124 (33.9)	165 (44.1)

MA05.01 A Systematic Approach to Appropriate Guideline-Based Management of Incidentally Detected Pulmonary Nodules the Mayo Clinic Experience

R. Anderson, B. Bartholmai, D. Christopherson, T. Peikert, M. Dulohery Scrodin
Mayo Clinic, Rochester/MN/USA

Introduction: Pulmonary nodules are detectable in approximately 50% of the general population. With increased utilization of modern cross-sectional chest imaging, incidentally detected pulmonary nodules (IPN) continue to increase. While the Fleischner Society guidelines provide the framework for appropriate follow-up, operationalizing guideline-based follow up remains challenging and burdensome to the healthcare system. According to previous studies, only 10-50% of patients with IPN are managed according to current guidelines. This lack of guideline based follow up can lead to increased morbidity and mortality due to delayed cancer diagnoses, increased patient anxiety, and health care cost.

Methods: A quality-improvement project was conducted at the Mayo Clinic in Rochester MN (USA) to evaluate the use of a third-party commercial vendor's product to improve guideline-based management of IPN. This software uses natural language processing to analyze all cross-sectional imaging reports capturing the lungs performed for any indication in any care location including inpatient, outpatient, and the emergency department. NLP identified the notation of lung nodules by the interpreting radiologist and then flagged these reports for further review. Scan reports were excluded if the patient was actively treated for cancer, or the scan was requested by a provider in oncology or in the pulmonary practice. Utilizing adapted Mayo Clinic IPN management guidelines (based on Fleischner guidelines) a team of Mayo-accredited registered nurses (provided by the third-party vendor) communicated appropriate management recommendations to the patient and their primary care providers. A lung nodule expert was available to the nurses for management questions for nodules that did not fit standard categories. If that primary care provider (PCP) was within Mayo Clinic, management recommendation-based orders were pre-scripted for their review and signature. If the PCP was outside of Mayo Clinic, the recommendation was communicated for follow up.

Results: Between December 2023 and March 2025, 25,944 patients with IPN were identified in the Mayo Clinic Rochester practice. 4,875 patients are currently under surveillance. This includes 4038 (84%) IPNs with appropriate initial IPN evaluation /follow up initiated by their Mayo Clinic PCP. For the remaining 837 (16%) patients nurse navigators facilitated guideline based follow up. This resulted in the identification of 8 new cancers, including primary lung and metastatic disease. The diagnostic workup of these patients included 167 CT scans, 21 PET-CT scans, 2 bronchoscopic and 1 CT guided biopsy, 63 referrals to the pulmonary lung nodule clinic. One patient underwent surgical resection, 5 were referred to radiation and 7 to medical oncology.

Conclusions: PCP-based initial management of IPN at Mayo Clinic was better than expected. Yet, despite that, the implementation of this program already helped to identify 8 new cancers by re-engaging 837 additional patients. Program implementation was simple, reduced workload burden on the care team, and was received positively by the care team all leading to improved IPN management and incidental cancer diagnosis.

MA05.02 The Preliminary Results of Taiwan National LDCT Lung Cancer Screening for Smokers and Nonsmokers With a Family History of Lung Cancer

P.C. Yang[1], Y-Z. Ho[2], T.H-H. Chen[3], Y-C. Chang[1], K-P. Huang[2], J-F. Wang[2], Y-T. Chunglo[2], Y-Y. Chen[4], Y-J. Yan[4], P-W. Yeh[4], C-Y. Huang[2], P-C. Hsieh[2], L-J. Lin[2], Y-R. Wang[2], S-L. Wei[2], C-C. Wu[2]
[1]National Taiwan University College of Medicine, Taipei/TW ,[2]Health Promotion Administration, Ministry of Health and Welfare, Taiwan, Taipei/TW ,[3]Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University,, Taipei/TW ,[4]Taiwan Radiological Society, Taipei/TW

Introduction: Lung cancer is the leading cause of cancer-related mortality worldwide. While smoking remains the primary risk factor, lung cancer among nonsmokers is increasing, accounting for over 30% of global lung cancer deaths. In Taiwan, more than 60% of lung cancer patients have no history of smoking, and a family history of lung cancer (LCFH) may elevate the risk. This study reports the implementation and initial two-year findings of a low-dose computed tomography (LDCT) lung cancer screening program targeting heavy smokers and nonsmokers with a LCFH, assessing stage-shifting and the anticipated long-term impact on reducing advanced disease and mortality.

Methods: The Taiwan National Lung Cancer Early Detection Program (TNLCEDP), a large-scale, biennial LDCT screening initiative, was launched on July 1, 2022, to offer screening to heavy smokers (≥30 pack-years) and nonsmokers (including light smokers) with a LCFH. In addition to evaluating basic screening outcomes, we assessed changes in lung cancer staging before and after the introduction of TNLCEDP. To simulate a randomized controlled trial, a pseudo-control study was conducted using a five-state stage-based disease natural history model, incorporating Markov machine learning algorithms trained on first-round screening data and lung cancer incidence statistics from the national cancer registry prior to TNLCEDP. This model was employed to estimate the long-term effectiveness of biennial LDCT screening over a six-year period, followed by a five-year follow-up. Here, we report the initial screening results from the first two years and evaluate the reduction in stage II+ cases and lung cancer mortality in both target groups, accounting for potential over-detection due to screening.

Results: A total of 108,720 individuals underwent their first LDCT screening, including 63,175 males (58.1%) and 45,545 females (41.9%). Of these, 45,601 (41.9%) were heavy smokers, 59,038 (54.3%) were nonsmokers with a LCFH, and 4,081 (3.8%) had both risk factors. Lung cancer was confirmed in 1,389 individuals, with 83.2% detected at stage 0-1 (stage 0: 8.8%, stage I: 74.4%). The overall detection rate was 1.3%, with higher rates in individuals with a LCFH (1.7% overall; 1.8% in nonsmokers and 1.1% in light smokers) compared to heavy smokers (0.8%) and those with both risk factors (1.1%). A substantial shift toward earlier-stage lung cancer detection was observed following screening. The projected long-term benefits of biennial screening include a 72% (67.7%-75.8%) reduction in advanced-stage lung cancer for nonsmokers with a LCFH and a 43.3% (35.0%-50.6%) reduction for heavy smokers. Corresponding mortality reductions were estimated at 66.7% (66.1%-67.2%) for nonsmokers with a LCFH and 35.6% (34.7%-36.4%) for heavy smokers, accounting for over-detection rates of 28.9% in heavy smokers and 14.4% in nonsmokers with a LCFH. The predicted mortality reduction in heavy smokers aligns with findings from the NELSON randomized controlled trial.

Conclusions: The TNLCEDP demonstrated significant early-stage detection and projected long-term benefits in reducing lung cancer mortality for heavy smokers and nonsmokers or light smokers with a LCFH, even after considering over-detection. The inclusion of nonsmoking individuals with a LCFH is crucial and may provide valuable insights for other countries considering the implementation of similar LDCT screening.

MA05.04 SENTINL0 Systemwide Early Notification Tool for Imminent Nascent Lung Cancer

A. Krule, A. Zakkar, V. Narra, D. Kim, M. Burrage-Burton, V. Gadi, R.H. Nguyen, A. Salahudeen
University of Illinois at Chicago, Chicago/IL/USA

Introduction: Early detection for lung cancer through low-dose computed tomography (LDCT) screening significantly improves survival rates. However, racial and ethnic disparities persist due to differences in access, adherence, and eligibility criteria that are largely based on non-Hispanic White cohorts. AI-driven models, such as Sybil, a validated Resnet18 3D neural network trained on the National Lung Screening Trial LDCT images, have demonstrated the ability to predict lung cancer risk from LDCT scans, yet their performance in diverse populations remains uncertain. This study evaluates whether Sybil, applied to prior available thoracic imaging, can predict lung cancer development relative to standard LDCT screening. By assessing the model's efficacy in a racially diverse cohort, we aim to determine if AI-driven risk stratification can enhance screening effectiveness, reduce disparities, and improve personalized screening strategies.

Methods: This ambidirectional, prospective-retrospective study analyzed patients who underwent lung cancer screening (LCS) at University of Illinois Health system (UIH). Multimodal AI inference (Zakkar et al. MedRxiv, 2024) was used to predict lung cancer risk from clinical and radiographic features. Outcomes of lung cancer diagnosis was determined by review of Electronic Health Record.

Results: At the time of this analysis, a total of 1,584 individuals who underwent LDCT procedures were included, with a median follow-up period of approximately six months. The predictive model demonstrated strong discriminative ability, achieving a Receiver Operating Characteristic (ROC) Area Under the Curve (AUC) of 0.82.Precision-recall analysis resulted in an Area Under the Curve (PR AUC) of 0.41. At a sensitivity threshold of 0.79, the model achieved a specificity of 0.96. Additionally, the positive predictive value (PPV) was 0.26 while the negative predictive value (NPV) was 0.97

Conclusions: In this interim analysis of diverse lung cancer screening patients, preliminary findings show multimodal AI has promising predictive ability of diagnosed lung cancer. These results highlight the model's effectiveness in distinguishing cases with a high degree of specificity and negative predictive value, making it a potentially valuable tool in clinical decision-making for LDCT-based assessments. Long-term follow up to ensure accuracy of complete diagnostic workups are required to definitively assess performance.

MA05.05 Analysis of Longitudinal Low-Dose CT Sybil Scores in Two Canadian Cohorts

C.H. Durney[1], S. Atkar-Khattra[2], S. Lam[2,3], R. Meza[2,3]
[1]BC Cancer Research Institute, Vancouver/BC/CA ,[2]British Columbia Cancer Research Institute, Vancouver/BC/CA ,[3]University of British Columbia, Vancouver/BC/CA

Introduction: Sybil is a deep learning model developed to predict lung cancer risk using a single low-dose computed tomography (LDCT) scan, without requiring clinical data. While prior studies have validated its predictive accuracy, time-patterns in Sybil scores from single-patient longitudinal LDCT scans, and variability of scores across risk groups remain under-explored. Understanding these is critical to assess the potential of Sybil for clinical use. We thus conducted an analysis of longitudinal Sybil risk scores using data from two Canadian lung cancer screening cohorts.

Methods: We analyzed LDCT imaging and clinical data from 2537 participants in the Pan-Canadian Early Detection of Lung Cancer Screening Study and 2110 participants in the British Columbia Lung Screening Study. Screening eligibility criteria were: age 50-75 with PLCOm2008 risk score 2%, and 50-80 years with a PLCOm2012 risk score of >1.51% over 6 years and/or USPSTF 2013 criteria, respectively. On average, cancer cases had 3.3 scans and non-cases had 2.96 scans per patient. A total of 270 (179,91 respectively) lung cancer cases were detected. Sybil scores were computed for each LDCT scan and trajectories were examined for individuals who developed lung cancer (cases) and those who did not (non-cases). We investigated how Sybil scores evolved relative to the time of diagnosis, age at baseline, and smoking status.

Results: Sybil scores were consistently higher for individuals who developed lung cancer compared to those who remained cancer-free (Figure 1A, $p < 0.001$). Among cases, mean/median Sybil scores increased as time to diagnosis decreased (Figure 1B). However, there was high heterogeneity in trajectories, with some cases having decreasing scores, and some non-cases having increasing scores (Figure 1A). Notably, we observed an age effect among cases: Sybil scores rose with increasing age at scan, a pattern not observed among controls, whose scores remained relatively flat across age (Figure 1C). When stratified by smoking status, both current and former smokers who developed lung cancer exhibited similar Sybil score trajectories.

Conclusions: Our analysis suggests that Sybil scores differentiate in aggregate individuals at risk of lung cancer with average scores increasing as diagnosis approaches. The model appears robust to smoking status and reflects subtle age-related risk dynamics in cancer cases, suggesting it detects radiographic features of malignancy independent of risk factors. These findings support a potential role of Sybil in risk stratification. However, the large heterogeneity in individual trajectories indicates that further refinements might be needed before clinical use.

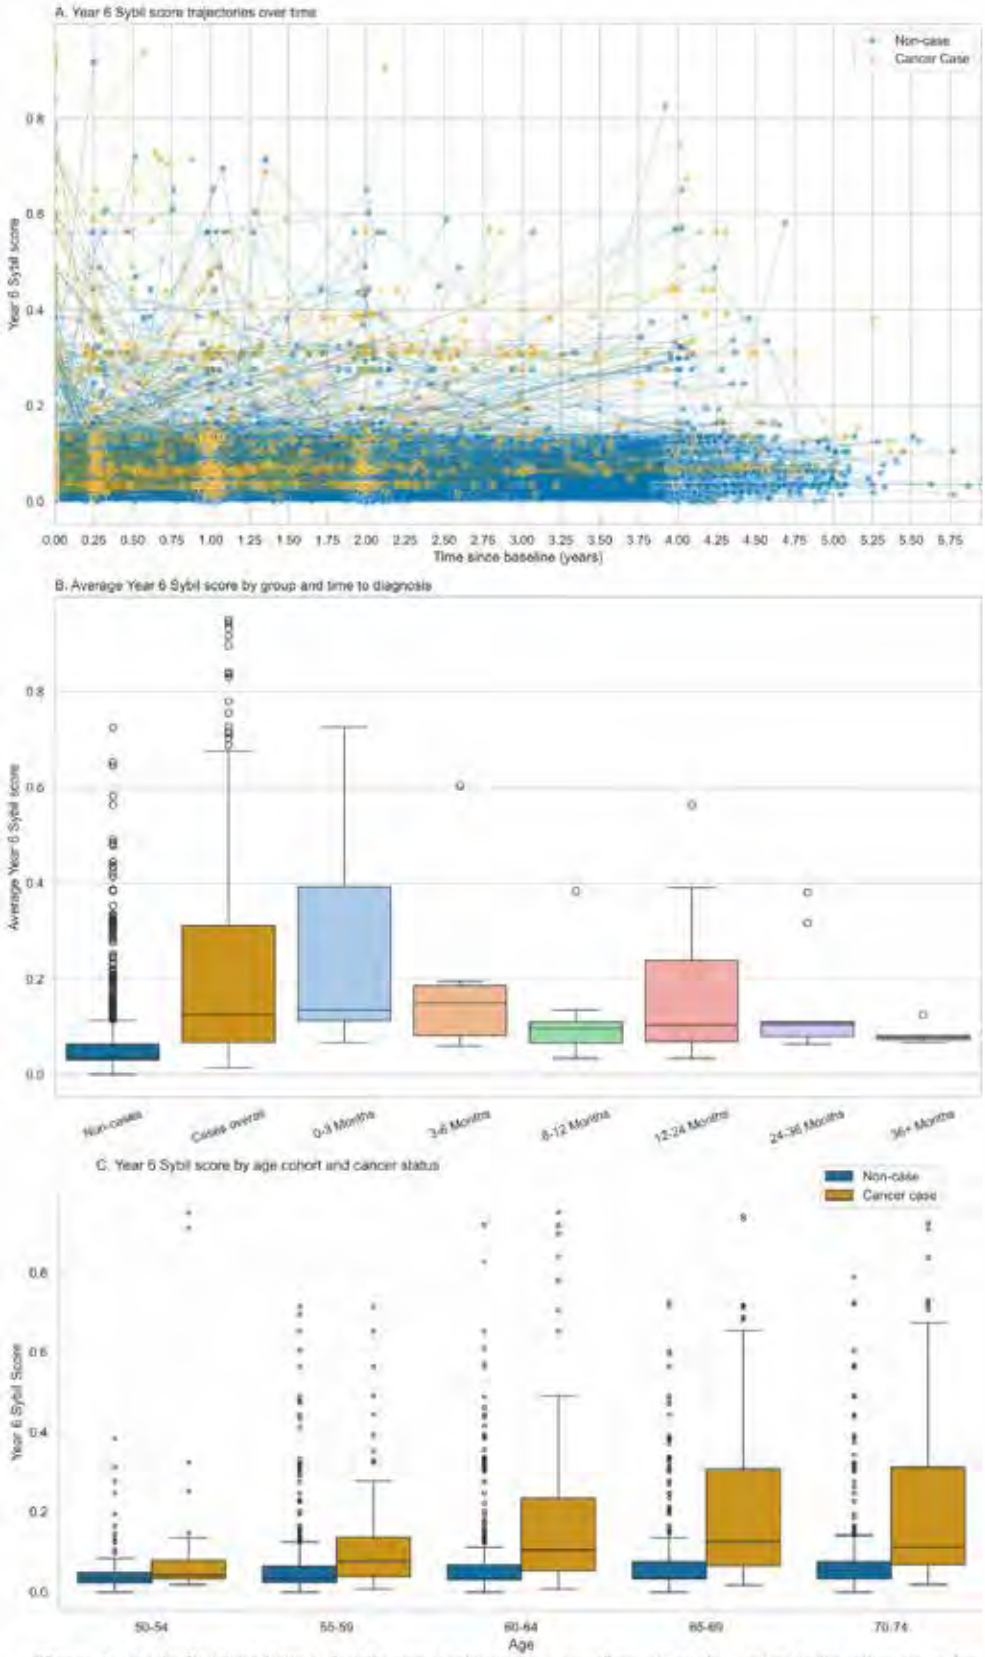

Figure 1: (A) Individual Year 6 Sybil score trajectories over time since the patient's baseline scan for cancer cases and non-cases. Each line represents a single participant. (B) Distribution of Year 6 Sybil scores by group. Cancer cases are further stratified by time from scan to diagnosis. (C) Distribution of Year 6 Sybil score stratified by age at scan and cancer status. Cancer Case refers to individuals diagnosed with lung cancer during follow-up; Non-case refers to those not diagnosed.

[1]Lunenfeld-Tanenbaum Research Institute, Toronto/ON/CA ,[2]University of Toronto, Toronto/ON/CA ,[3]University of Pittsburgh, Pittsburgh/PA/USA ,[4]UPMC Hillman Cancer Center, Pittsburgh/PA/USA ,[5]British Columbia Cancer Agency, Vancouver/BC/CA ,[6]University of Liverpool, Liverpool/GB ,[7]Princess Margaret Cancer Center, Toronto/ON/CA ,[8]University of Navarra, Pamplona/ES ,[9]Pamplona and CIBERONC, Madrid/ES ,[10]Baylor College of Medicine, Houston/TX/USA ,[11]International Agency for Research on Cancer, Lyon/FR

Introduction: Low-Dose Computed Tomography (LDCT) screening can significantly improve early lung cancer detection and reduce its mortality. However, it remains a challenge to optimize the clinical management of pulmonary nodules detected within screening programs. Our previous work identified a set of informative circulating protein markers for predicting pulmonary nodule malignancy. In this study, we evaluated whether incorporating these circulating protein biomarkers along with clinical, epidemiological and image data could enhance the predictive accuracy of risk models for pulmonary nodules.

Methods: This study is part of the Integrative Analysis of Lung Cancer Risk and Etiology (INTEGRAL) research program and is based on data from 5 LDCT screening programs in US, Canada and Europe with a total of 2,039 participants (683 cancer patients, 687 frequency matched controls with benign nodules and 669 healthy controls without nodules, nested in the same cohort). From a proteomic screening of over 1,100 circulating protein markers, 21 top-performing markers were selected in collaboration with the Lung Cancer Cohort Consortium, including six population-based cohorts. These 21 selected proteins were then quantified using absolute values. Model development was conducted using data from four LDCT screening studies: Pan-Canadian Early Detection of Lung Cancer Study (PanCan), International Early Lung Cancer Action Program (IELCAP)-Toronto, UK Lung Cancer Screening Trial (UKLS), and Pamplona-IELCAP. The model was externally evaluated in an independent cohort, the Pittsburgh Lung Screening Study-PLuSS (258 cancer patients, 257 frequency-matched controls with benign nodules).We identified the top-performing sets of protein markers using a support vector machine-recursive feature elimination (SVM-RFE) approach. For each set, we trained models to predict the risk of a benign nodule becoming malignant within five years post screen using machine learning (ML) approaches. ML models included logistic regression, random forest, and support vector machine (SVM), with logistic regression achieving the highest area under the receiver operating characteristic curve (AUC) when combined with epidemiological and imaging features through an ensemble approach. The final model was recalibrated using a logistic recalibration method.

Results: In the independent validation set, the INTEGRAL-Proteins for Nodules (INTEGRAL-PEN) model demonstrated strong predictive performance, with an overall AUC of 0.87 (95%CI=0.83-0.90) and 0.80 (95%CI=0.77-0.83) for predicting malignancy within the first- and 5-years post screen, respectively. Our model significantly outperformed both the Brock/PanCan model (AUC=0.74) and Lung Imaging Reporting and Data System (LungRADS) (AUC=0.65) in predicting malignancy up to 5 years post screen. Compared to the other risk assessment approaches, the INTEGRAL-PEN model performed better at identifying cancers among small nodules (<10mm), among those with longer follow-up (>1 year), and at identifying early-stage lung cancers. Those without nodules have similar protein profiles to those with benign nodules. This finding suggests that the protein profiles we identified are specific to the presence of malignant nodules, not just to the presence of any type of nodules.

Conclusions: The INTEGRAL-PEN model, validated in an external cohort, demonstrated strong performance in distinguishing malignant from benign pulmonary nodules. These findings highlight the added value of circulating protein biomarkers in improving nodule stratification in lung cancer screening.

MA05.07 Breathomics for Early Non-Invasive Detection of Lung Cancer: A Propectively Multicenter Study Using TD-GC-MS and Portable Micro-GC

R. Wang[1], H. Liang[1], M. Peng[2], B. Tian[3], P. Fan[2], H. Wang[2], S. Chen[2], Z. Chen[4], R. Zhong[1], X. Fan[1], A. Ailifeire[1], S. Yang[4], Q. Li[3], J. Wang[2], J. He[1]
[1]the First Affiliated Hospital of Guangzhou Medical University, Guangzhou/CN ,[2]ChromX Health Co., Ltd, Guangzhou/CN ,[3]Sichuan Clinical Research Center for Cancer, Sichuan Cancer Hospital & Institute, Sichuan Cancer Center, Affiliated Cancer Hospital of University of Electronic Science and Technology of China, Chengdu/CN ,[4]the First People's Hospital of Foshan, Foshan/CN

Introduction: This study evaluates the diagnostic accuracy of breathomics, using TD-GC-MS for model development and a portable micro gas chromatography- micro photoionisation detector (µGC-µPID) system for validation, to establish a non-invasive, accessible lung cancer screening method aimed at reducing mortality rates and healthcare costs of late-stage lung cancer.

Methods: A prospective, multicenter study enrolled 5,292 participants across four hospitals, including 1,676 lung cancer patients and 4,616 controls (472 healthy individuals, 2,993 with chronic respiratory diseases). Thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS) analysis of exhaled breath samples, with feature selection via orthogonal partial least squares discriminant analysis, was used to train (n=2,132) and internally validate (n=719) a logistic regression model. External validation (2,441 samples) used data from the portable µGC-µPID system, which integrates three microfabricated chips for volatile organic compound capture, separation, and detection.

Results: Fourteen breathomic biomarkers were identified for distinguishing lung cancer patients from controls. In internal validation, the model achieved an AUC of 0.91 (95% CI: 0.88-0.94), accuracy of 78%, sensitivity of 95%, specificity of 60%, and a Negative Predictive Value (NPV) of 91%. External validation using the µGC-µPID system confirmed these results, with an AUC of 0.87, accuracy of 51%, sensitivity of 91%, specificity of 45%, and NPV of 96%. The model demonstrated high sensitivity in detecting lung cancers of various sizes, particularly excelling in identifying lesions smaller than 10 mm (AUC 0.92, sensitivity 98.2% internally; AUC 0.90, sensitivity 92.8% externally) and AJCC stage IA1 lung cancer (sensitivity 95.5% internally and 94.8% externally). In a real-world screening subset of the external validation group (n=2,055), the model correctly identified 80% of lung cancer cases and excluded 45.7% of non-cancer individuals.

Conclusions: This largest-scale study to date demonstrates the potential of machine learning-enhanced breathomics as a highly sensitive and non-invasive approach for early lung cancer detection. Utilizing portable µGCs, this cost-effective screening method offers feasible deployment across diverse clinical settings, particularly benefiting high-risk populations by minimizing radiation exposure and improving access to care. By facilitating earlier diagnosis, breathomics has the potential to significantly reduce lung cancer mortality and enhance quality of life, supporting its integration into public health strategies.

MA05.08 Cell-Free DNA Methylation Markers in Serum and Bronchial Washing for Lung Cancer Detection: A Prospective Observational Study

Y. Song[1], H.S. Kwak[1], Y. Seo[2], S. Jang[2], S. Kim[2], C-M. Choi[1], T.J. Oh[2], S. An[2], W. Ji[1]
[1]Asan Medical Center, University of Ulsan College of Medicine, Seoul/KR ,[2]Genomictree Inc, Daejeon/KR

Introduction: In the era of lung cancer screening, the use of peripheral bronchoscopy has increased due to the rising detection of small peripheral lung nodules. However, the development of biomarkers for the early and accurate diagnosis of lung cancer using bronchial washing (BW) specimens remains a clinical challenge. This study aimed to evaluate the clinical utility of DNA methylation markers in serum and BW samples for distinguishing malignant from benign pulmonary nodules detected through chest CT screening.

Methods: We prospectively enrolled 200 individuals with pulmonary nodules between May 2024 and February 2025 at Asan Medical Center, South Korea. Clinical demographics, nodule characteristics, and methylation profiles of 4 genes (PCDHGA12, OLIG3, NKX2-5, FOXC2) in serum, and 2 genes (PCDHGA12, PRRX1) in BW samples were analyzed. Diagnostic performance was evaluated using ROC curve analysis, and the association between methylation status and clinicopathologic features was also assessed.

Results: Among 200 initially enrolled participants, 9 were excluded due to the diagnosis of other malignancies or withdrawal of informed consent. The final analysis included 191 patients (123 with malignancy, 68 with benign nodules). Patients with malignancy were older (median age 70 vs. 64 years, $p < 0.001$) and had a lower BMI (mean 23.1 vs. 24.8 kg/m^2, $p = 0.046$). Malignant nodules were larger (mean size 29.3 mm vs. 18.0 mm, $p < 0.001$) and had significantly higher Lung-RADS categories ($p < 0.001$). Adenocarcinoma was the most common malignant histology (77 of 123, 62.6%), while inflammatory nodules (26 of 68, 38.2%) were the most frequent etiology in the benign group. The serum based 4 gene methylation panel demonstrated an AUC of 0.600 (95% CI, 0.526 - 0.671), with 80.0% sensitivity and 40.0% specificity. The BW based 2 gene panel showed superior diagnostic performance, with an AUC of 0.785 (95% CI, 0.687 - 0.864), 74.7% sensitivity, and 82.4% specificity. Methylation positivity in serum samples was observed in 80.0% of lung cancer patients and was not significantly associated with age, sex, tumor location, histology, or stage. Similar trends were observed in BW samples.

Conclusions: Cell-free DNA methylation panels using serum and bronchial washing specimens demonstrated promising diagnostic performance for lung cancer detection. Notably, the 2 gene panel in bronchial washing samples showed higher diagnostic accuracy than the serum panel, supporting its potential as a useful diagnostic tool for early lung cancer detection in clinical practice.*English language editing was assisted by the AI tool ChatGPT-4.

MA05.09 Precise Diagnosis of Small Malignant Pulmonary Nodules Driven by Peripheral Single-Cell Immune Signatures: A Prospective Multi-Center Study

Y. Xia[1], Y. Zhu[1], S. Zhang[2], H. Shi[3], X. Le[4], T. Mok[5], J. Fan[2], W. Yin[6], W. Li[1]
[1]Second Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou City, Zhejiang Province/CN ,[2]Second Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou/CN ,[3]Zhejiang Puluoting Health Technology Co., Ltd, Hangzhou/CN ,[4]University of Texas MD Anderson Cancer Center, Houston/TX/USA ,[5]Chinese University of Hong Kong, Hong Kong/CN ,[6]Zhejiang University, Hangzhou/CN

Introduction: Early detection of pulmonary nodules is critical for improving outcomes in lung cancer patients. However, accurately diagnosing malignant nodules, especially those ≤10 mm, and predicting tumor invasiveness to guide surgical decisions remain significant challenges. Immune dysfunction is known to contribute to cancer development, and we hypothesize that alterations in peripheral blood immune profiles could provide a novel approach for the diagnosis and management of pulmonary nodules.

Methods: We conducted a prospective study involving three cohorts: healthy controls, individuals with pulmonary nodules, and patients with advanced lung cancer. Peripheral blood samples were collected and analyzed using mass cytometry to characterize immune signatures. Machine learning algorithms were applied to identify immune profiles associated with lung cancer, leading to the development of the SMART platform, driven by AI-mined single-cell immune signatures. This platform consists of two consecutive modules: the Diagnostic Decision (DIA) module for distinguishing malignant from benign nodules, and the Surgical Decision (SUR) module for predicting tumor invasiveness.

Results: A total of 1032 participants were recruited from three medical centers, with 930 blood samples qualified for analysis. The early-stage lung carcinoma (CA) and non-carcinoma (non-CA) nodule samples were divided into a training cohort (396 participants) and a testing cohort (408 participants). The DIA module achieved high accuracy in distinguishing malignant from benign nodules, with an AUC of 0.952 in the testing cohort, significantly outperforming existing models such as the Mayo (AUC = 0.751), Veterans Association (AUC = 0.733), and Brock (AUC = 0.840) models. The DIA module also performed well in an independent set, including healthy controls without pulmonary nodules and patients with advanced lung cancer (AUC = 0.945). For lung cancer samples (N = 435), the SUR module accurately differentiated minimal invasive adenocarcinoma (MIA) from invasive adenocarcinoma (IA), with AUCs of 0.984 in the training cohort (N = 218) and 0.949 in the testing cohort (N = 217), outperforming the average accuracy of experienced clinicians making assessments based on CT images and clinical data.

Conclusions: By leveraging peripheral blood immune profiles, we have developed the SMART platform, which effectively and accurately facilitates differential diagnosis of small pulmonary nodules and the assessment of lung tumor invasiveness. The SMART platform offers substantial clinical benefits and hold promise as a crucial tool in the comprehensive management of pulmonary nodules.

MA06.01 Real-World Outcomes of First-Line Immunotherapy Intensification of Patients With Advanced Non-Small Cell Lung Cancer (aNSCLC)

X. Wang[1], W. Wong[1], J.C.F. Quintanilha[2], R.P. Graf[2], A.C. Chiang[1], S.Y. Kim[1]
[1]Yale Cancer Center, New Haven/CT/USA ,[2]Foundation Medicine, Inc., Boston/MA/USA

Introduction: There are multiple first-line (1L) immune checkpoint inhibitor (ICI)-based treatment options for patients with aNSCLC. Intensification of ICI treatment from single ICI with chemotherapy (single ICI-chemo) to dual ICI regimens with (dual ICI-chemo) or without (dual ICI) chemotherapy has been suggested for patients with risk factors for ICI resistance, such as cancers with alterations in STK11/KEAP1. However, these intensified regimens have not been compared prospectively in either broad or selected at-risk populations.

Methods: We conducted a retrospective observational study of real-world 1L clinical outcomes data for United States (US) patients with aNSCLC who underwent tissue Foundation Medicine comprehensive genomic profiling, using the US-based deidentified Flatiron Health-Foundation Medicine NSCLC Clinico-Genomic Database. We categorized patients diagnosed 2020-2024 by 1L regimen (single ICI-chemo, dual ICI-chemo, dual ICI) and propensity weighted by age, ECOG performance status, PD-L1, liver/brain metastasis, practice setting (academic/community), smoking status, and year of diagnosis. We then calculated time-to-next treatment (TTNT), real-world progression-free survival (rwPFS), and overall survival (OS) by multivariable Cox proportional hazards regression, adjusting for histology and alterations in TP53, KRAS, and STK11/KEAP1, as well as the interaction between STK11/KEAP1 alteration and treatment.

Results: Our samples included 1,703 patients (median age 69.0 years, 44.9% female; 88.6% single ICI-chemo, 4.3% dual ICI-chemo, 7.1% dual ICI). Overall, dual ICI-chemo was associated with worse rwPFS compared to single ICI-chemo (HR 2.20, p < .001), though this difference was not seen in TTNT (p = .72). No differences were seen in OS (median OS 11.9 months single ICI-chemo, 7.4 months dual ICI-chemo, 9.7 months dual ICI; all p > .05). STK11/KEAP1 alteration status (HR 1.32, p < .001) and squamous histology (HR 1.36, p < .001) were associated with worse OS in multivariable analysis, though the interaction of STK11/KEAP1 alteration and treatment was not significant (p > .1).

Conclusions: In this large, real-world cohort of US patients with aNSCLC, similar clinical outcomes were seen between all three 1L treatment regimens, suggesting that patients exposed to potentially more toxic and costly regimens did not derive additional clinical benefit. STK11/KEAP1 alteration status had an independent association with worse OS but was not associated with a differential benefit in ICI intensification. Further prospective studies are needed to identify appropriate patients for ICI intensification.

	Median TTNT	HR (95% CI)	P value
Single ICI + chemo	7.1	Ref	
Dual ICI + chemo	4.7	1.15 (0.53-2.49)	0.7253
Dual ICI	8.5	1.23 (0.89-1.71)	0.2151

	Median PFS	HR (95% CI)	P value
Single ICI + chemo	5.6	Ref	
Dual ICI + chemo	3.2	2.20 (1.61-3.02)	<0.001
Dual ICI	6	1.30 (0.91-1.84)	0.1491

	Median OS	HR (95% CI)	P value
Single ICI + chemo	11.9	Ref	
Dual ICI + chemo	7.4	0.97 (0.50-1.85)	0.9221
Dual ICI	9.7	1.27 (0.88-1.82)	0.2005

MA06.02 Paradigm Shift in Lung Cancer Mortality in the United States: A Multifaceted Success Story

M.R. Islam[1], S.M. Siddiqua[2], H. Islam[1], A. Craver[1], H. Ahsan[1]
[1]University of Chicago, Chicago/IL/USA ,[2]Unity through population, Dhaka/BD

Introduction: Lung cancer remains the second most diagnosed cancer in the United States and the leading cause of cancer-related deaths. While mortality rates have declined over the past two decades, the extent of this decline varies by gender and socio-economic factors. Research suggests that disparities in lung cancer outcomes are influenced by economic development, healthcare accessibility, policy regulations, and environmental exposures. This study explores the role of socio-economic indicators, policy-level factors, and environmental influences, such as air pollution, in shaping lung cancer mortality trends. By analyzing publicly available data on lung cancer deaths, healthcare expenditures, smoking trends, and air quality, we aim to understand the key drivers behind the reduction in lung cancer mortality in the United States.

Methods: We conducted an ecological study analyzing lung cancer mortality trends in the United States over the past two decades. Data on lung cancer mortality were obtained from the Cancer Over Time database. At the same time, socio-economic indicators such as the Human Development Index (HDI), Gini coefficient, and healthcare expenditure inflation were sourced from publicly available repositories, including the United Nations Development Programme and World Bank. Environmental data, including PM2.5 levels, were collected from the State of Global Air database. Using statistical modeling and trend analysis, we examined the associations between lung cancer mortality and these factors. Since all data were publicly available, ethical approval was not required.

Results: Joinpoint regression analysis revealed substantial declines in lung cancer Age-Standardized Mortality Rates (ASMR) from 1994-2020, with male mortality decreasing by 58.9% and female mortality by 40.3%. The most accelerated declines occurred after 2014, coinciding with the FDA approval of 30 new lung cancer drugs during the study period. Male mortality decline accelerated from -2.31% (1994-1998) to -5.62% (2014-2018), while female mortality remained stable until 2004 before declining, reaching -4.43% (2014-2018). The male-to-female mortality gap narrowed from 1.98:1 in 1994 to 1.36:1 in 2020. Histological analysis showed gender-specific trends, with adenocarcinoma increasing 7.4% in females while declining 28.5% in males. Smoking prevalence decreased substantially (males: 47.8%, females: 51.3%), with regression analysis revealing stronger associations between smoking and mortality in males (coefficient=2.14, $p<0.001$) than in females (coefficient=0.97, $p<0.001$). Ridge logistic regression identified smoking as increasing mortality risk by 3 times in males and 5.7 times in females. PM2.5 concentration declined from 13.8 $\mu g/m^3$ to 7.81 $\mu g/m^3$, with environmental exposure more strongly associated with male mortality ($\beta=4.11$, $p<0.001$) compared to females ($\beta=1.48$, $p<0.001$). HDI showed a negative correlation with mortality rates ($r=-0.61$), while healthcare inflation demonstrated a weaker positive correlation ($r=0.34$). Despite doubling healthcare expenditure and reducing uninsured rates from 15.2% to 8.6%, the Gini index remained relatively stable (39.7 to 41.5), suggesting persistent socioeconomic disparities alongside improved healthcare access.

Conclusions: The significant reduction in U.S. lung cancer mortality over three decades results from a comprehensive multisectoral approach combining environmental controls, anti-tobacco campaigns, healthcare reforms, and precision medicine advances. Despite this progress, further improvements require addressing four key areas: expanding equitable access, implementing value-based care, strengthening prevention, and ensuring fair distribution of personalized treatments.

Introduction: Neoadjuvant and perioperative chemoimmunotherapy is increasingly used in resectable NSCLC. Several trials achieved improvement in EFS and OS, and most used a perioperative strategy. There is poor compliance of post-op IT and its duration and value is not well established. Until now there are no cost-value analysis of these approaches. Here, we report a pharmacoeconomic analysis of NADIM 2 trial.

Methods: 86 patients with resectable Stage IIIA/B NSCLC were randomly assigned in a 2:1 ratio to receive 3 cycles of preoperative nivolumab plus chemotherapy (experimental group, Exp) versus chemotherapy alone (control group) and after R0 surgery, patients assigned to Exp arm received nivolumab monthly for 6 months (m). Improvement in OS (secondary end-point) was observed after a median follow-up of 22.6 m improving 14 m OS from 63.6 % to 85% (NEJM 2023;389:504-513). Nivolumab was administered at flat dose of 360 mg preop and 480 mg postop. An intention to treat analysis was performed using patient crude survival time and cost of delivered immunotherapy according to nivolumab price in Spain.

Results: Only 2 out of 57 p do not received 3 preoperative treatment cycles. 36/57 p (63%) completed planned postop Nivolumab. 11 p (19%) do not received any postoperative dose. Overall, the delivered doses of Nivolumab achieved 72% of planned treatment. The mean survival in the Exp group was 41.7m vs 21.3m in Control with an increase of 20.3m. Total cost of nivolumab treatment per protocol accounted for 50,371€, while the cost of delivered treatment was 31,016€. After adjusting for OS, the benefit per patient resulted in 18,299€ per gained year of life.

Conclusions: Perioperative chemo-immunotherapy is the current standard of care in resectable Stage III NSCLC and improved OS in NADIM 2 trial. Compliance of post-operative immunotherapy was 72% of planned dose. Cost per life years gained of 3 cycles pre and 6 cycles postop Nivolumab accounts for 18.299 € below the threshold of cost-effectiveness accepted in most European countries.

MA06.04 Improving Preoperative ctDNA Detection in NSCLC Through Mechanistic Profiling and Multiregion-Informed Customization

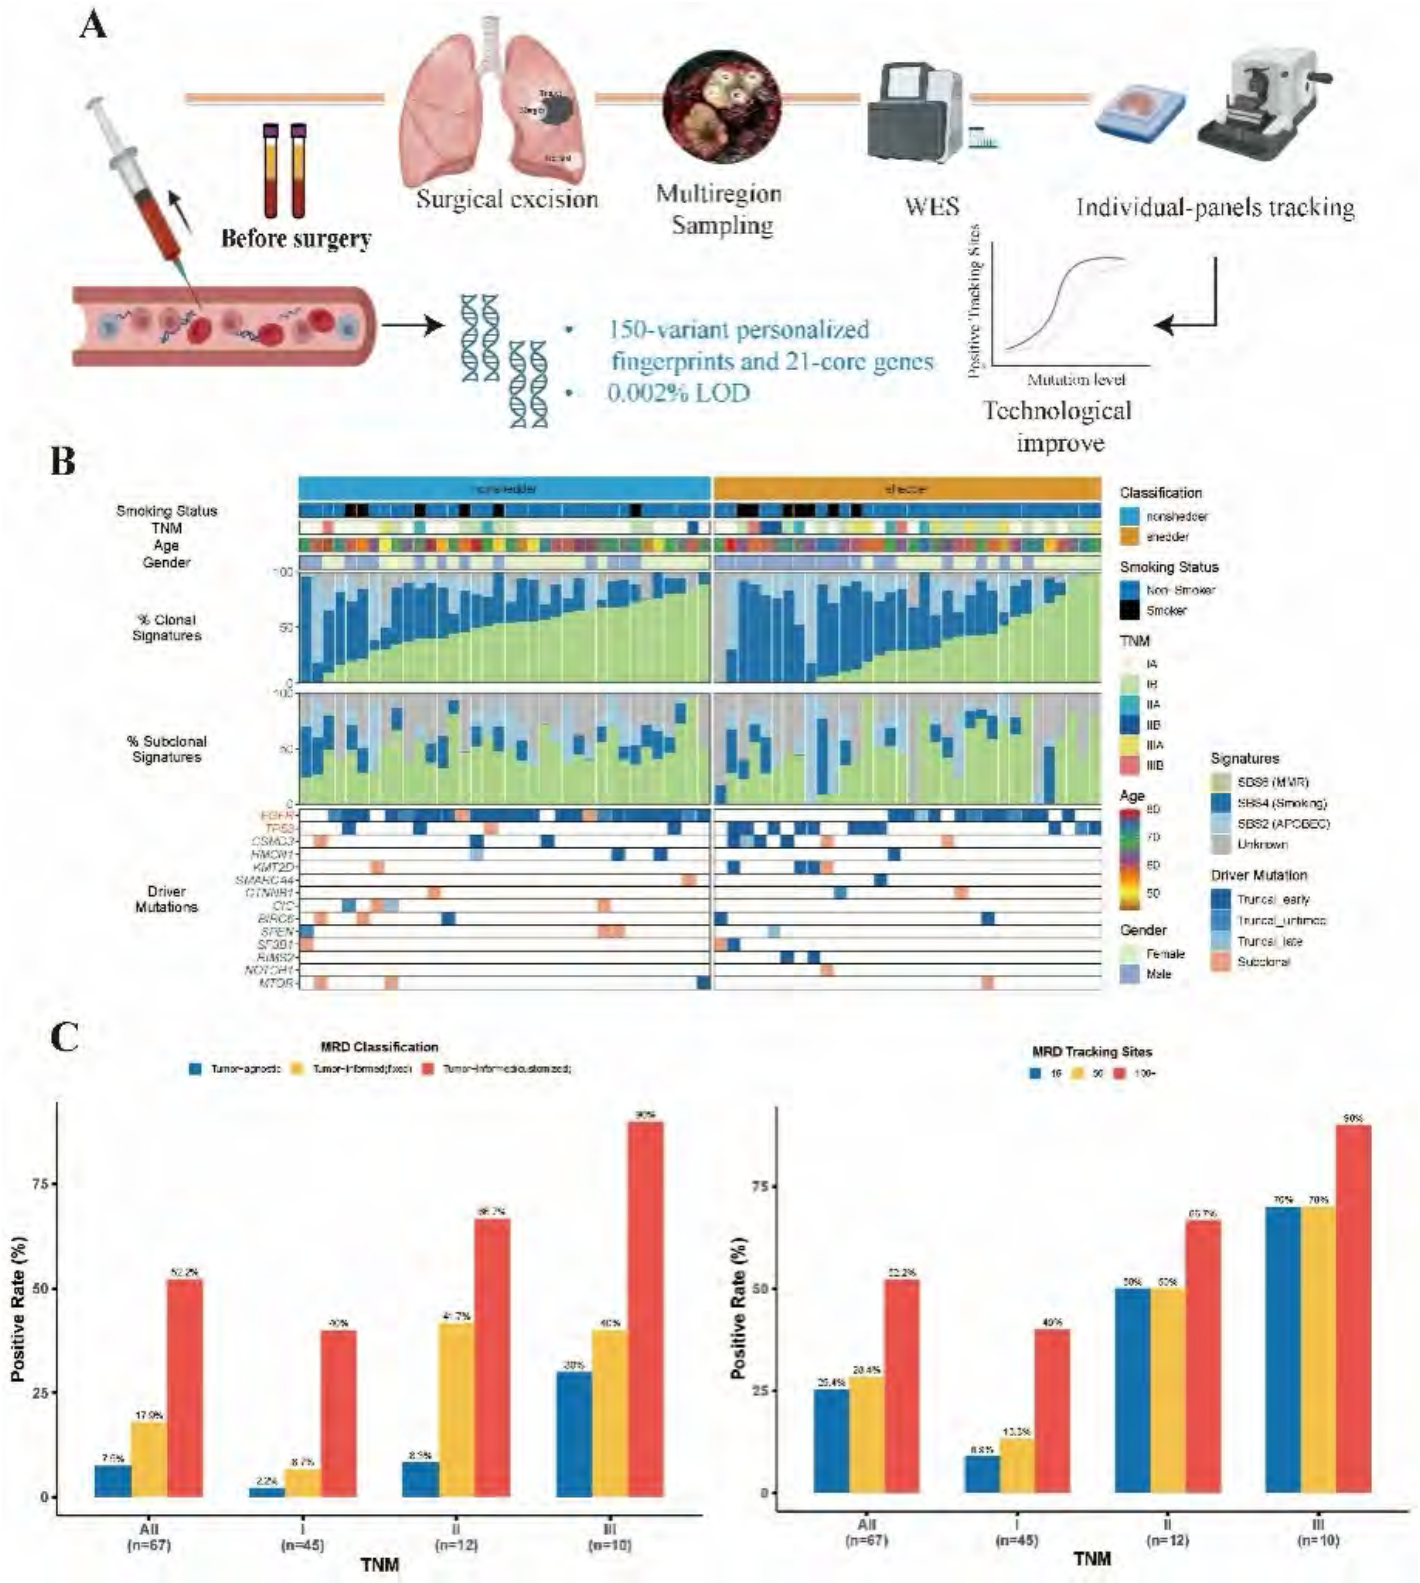
Y. He[1,2], W. Wang[1,2], Z. Li[1,2], J. Xu[3], S. Lu[1], J. Bai[3], K. Chen[1,2]
[1]Peking university people's hospital, Beijing/CN ,[2]Chinese Academy of Medical Sciences, Beijing/CN ,[3]Kanghui biotech, Beijing/CN

Introduction: Circulating tumor DNA (ctDNA) is a highly promising biomarker for the precise management of NSCLC, yet its clinical utility remains limited by technical challenges. Preoperative ctDNA shedding has been associated with poorer prognosis, and numerous ongoing RCTs employing ctDNA to guide postoperative treatment underscore the need for enhanced detection sensitivity. In this study, we further investigated the mechanisms underlying nonshedding in certain patient populations.

Methods: We prospectively enrolled 73 patients with primary NSCLC. Preoperative blood samples were collected using cfDNA-free tubes, and intraoperative multi-region tumor sampling was performed for WES. Our platform, Variant-Integrated Genomic Insight for Longitudinal tracking (VIGIL™), integrates 150 personalized somatic variants and 21 core genes, including SNVs, indels, and fusions, achieving a LOD of 0.002%.

Results: Patients in the Shedder group—defined by detectable preoperative ctDNA—were more likely to be male and to present with solid lesions rather than ground-glass opacities. Consistent with previous studies, non-adenocarcinoma histology was more commonly observed in this group. The Shedders also exhibited a more activated immune microenvironment, characterized by enrichment of CD4+ T cells, γδ T cells, CD8+ memory T cells, and M1 macrophages. Preoperative ctDNA shedding was significantly associated with an increased risk of recurrence. EGFR mutations were more frequent in the Nonshedder group, whereas TP53 mutations predominated among Shedders; notably, these two driver mutations were mutually exclusive in the Shedder group. Retrospective probe analysis revealed higher levels of clonal neoantigens in Shedders and more subclonal neoantigens in Nonshedders, suggesting a stronger role for clonal neoantigens in facilitating ctDNA release across various evolutionary contexts. To enhance objectivity, we further analyzed a subset of 67 patients with over 100 mutation-tracking loci. Compared to fixed tumor-informed or tumor-agnostic approaches, the customized tumor-informed strategy significantly increased detection rates, particularly in stage I cases (40% detection). Moreover, increasing the number of tracking loci to over 100 nearly doubled detection sensitivity relative to 16 (TRACERx, 2017) or 50 (MEDAL, 2023) loci. This improvement is likely due to multi-region sampling and an increased number of tracking loci, which correct for clonal illusion and enable more comprehensive capture of both clonal and subclonal mutations.

Conclusions: This study refines the tumor-informed ctDNA detection strategy, effectively reducing false negatives in nonshedders and enhancing the robustness of ctDNA as a clinical biomarker. Although our findings are based on preoperative blood samples, the high sensitivity of this approach suggests strong potential for postoperative longitudinal monitoring as well.



Keywords: ctDNA, tumor-informed panal, NSCLC

MA06.05 Impact of Bronchoalveolar Lavage Combined With mNGS in Patients With Checkpoint Inhibitor Pneumonia: A Prospective Cohort Study

Z. Zhou, X. Huang, J. Li, L. Liu
Southern Medical University Nanfang Hospital, GuangZhou/CN

Introduction: Checkpoint inhibitor pneumonia (CIP) is a serious immune-related adverse event with high morbidity and mortality, currently lacking specific diagnostic methods and posing significant challenges in diagnosis and management. This study aims to investigate the value of bronchoalveolar lavage (BAL) combined with metagenomic next-generation sequencing (mNGS) in the diagnosis and precision treatment of CIP for providing evidence-based medicine.

Methods: This prospective clinical trial (NCT06192303) enrolled a total of 103 patients suspected checkpoint inhibitor pneumonia (CIP). Clinicians integrated patient clinical data and treatment outcomes to make final diagnosis, which included 35 cases of pure-type CIP (PT-CIP), 58 cases of mixed-type CIP (MT-CIP), and 10 cases of pulmonary infections (PI). We evaluated the diagnostic efficacy of BAL mNGS in CIP and explored the clinical characteristic differences among different subtypes of CIP patients. Additionally, receiver operating characteristic (ROC) analysis and logistic regression analysis was utilized to investigate the potential efficacy of immune-inflammatory markers in distinguishing MT-CIP from PI. Furthermore, the value of BAL mNGS in guiding treatment for CIP patients was assessed by the total time to relief to grade I or below, the short-term treatment effectiveness within 7 days, the proportion of relief within 3 months, and the intensity of antibiotic use during hospitalization.

Results: BAL combined with mNGS indicated high sensitivity and specificity in diagnosing CIP. 100%(20/20) of patients with negative mNGS results were finally diagnosed as pure-type CIP(PT-CIP), and 75.6%(31/41) of patients with positive mNGS results were finally diagnosed as mixed-type CIP(MT-CIP). Notably, 24.4%(10/41) of patients with positive mNGS results achieved recovery from targeted antibiotic therapy alone, avoiding unnecessary corticosteroid treatment. Immune-inflammatory markers, including ALC, NLR, MLR, PLR, and SII, showed significant diagnostic efficacy in distinguishing mixed-type CIP from pulmonary infections. Treatment guided by BAL mNGS significantly reduced the total recovery time of CIP patients, and improved both 7-days (90.2% vs 69.0%, P<0.05) and 3-months (58.1% vs 32.3%, P<0.05) outcomes. Furthermore, BAL mNGS-guided treatment increased antibiotic use intensity in severe CIP patients with Grade 3-4, highlighting its clinical utility in timely pathogen detection and targeted therapy.

Conclusions: This study demonstrated the critical role of BAL mNGS in enhancing CIP diagnosis, guiding treatment, and improving patient prognosis. A stratified treatment strategy based on BAL mNGS results and immune-inflammatory markers was proposed for advancing the management of CIP patients.

MA06.06 Overall Survival Among Patients With Oncogene Driven Lung Cancers Treated on Clinical Trials Compared to Standard Care

A. Sestito[1], J. Rogers[1], L. Selbie[1], D. Arasaratnam[1], J. Geng[1], C. Williams[1], T. Spelman[2], T. John[2], S. Harden[2], B. Solomon[2], M. Alexander[2]
[1]Peter MacCallum Cancer Centre, Melbourne/AU ,[2]Peter MacCallum Cancer Centre, Melbourne Australia, and Sir Peter MacCallum Department of Oncology, The University of Melbourne, Parkville/AU

Introduction: Targeted treatments for oncogene-driven lung cancers have transformed care and survival. While trials offer novel therapies and structured monitoring, real-world treatment varies. This study compared survival outcomes for patients on clinical trials versus standard-of-care (SOC) therapies.

Methods: This analysis includes patients with advanced/metastatic oncogene-driven NSCLC from the AUstralasian thoRacic cancers lOngitudinal cohoRt study and biobAnk (AURORA) at Peter MacCallum Cancer Centre (ACTRN12625000038493). Eligible patients (≥18 years) had ALK, BRAF, EGFR, ERBB2, KRAS G12C, MET14, RET, or ROS1 NSCLC diagnosed 2013-2023 and received ≥1 line of systemic therapy for advanced disease (early-stage treatments permitted). The primary endpoint, overall survival (OS), was defined from first-line treatment initiation to death or last follow-up. Kaplan-Meier estimates, log-rank tests, and multivariate Cox regression assessed survival differences and covariate effects (age, sex, mutation, stage, performance status). Exploratory analyses within larger EGFR, ALK, and KRAS G12C subgroups.

Results: Among 540 patients, 167 received clinical trial treatment and 373 SOC therapy. Trial patients were younger (mean 57±12.1 vs. 63±12.3 years, p<0.001) and fewer had ECOG≥2 (3% vs. 9%, p=0.01). Other demographics were similar: advanced-stage disease (IIIB, IIIC, IV) at diagnosis: 90% vs. 85%, female: 55% vs. 60%, never-smokers: 55% vs. 53%, White/Caucasian: 61% vs. 60%, Asian: 37% vs. 38%. Mutation distribution (N,%) in trial vs. SOC cohorts was: ALK (26,16% vs. 55,15%), BRAF (9, 5% vs. 19, 5%), EGFR (79, 47% vs. 223, 60%), ERBB2 (4, 2% vs. 3, 1%), KRAS G12C (25, 15% vs. 62, 17%), MET14 (0, 0% vs. 1, <1%), RET (4, 2% vs. 4, 1%), and ROS1 (20, 12% vs. 6, 2%). Median OS was longer in the trial cohort (44 months, 95%CI: 38-50) vs. SOC (27 months, 95%CI: 24-32) (univariate HR 0.71, 95% CI: 0.56-0.89, p=0.003; multivariate HR 0.78, 95%CI: 0.61-0.99, p=0.05). In adjusted analyses by mutation, EGFR OS was 40 months (95%CI: 33-49) in trials vs. 27 months (95%CI: 24-33) in SOC (HR 0.70, 95%CI: 0.51-0.97, p=0.035), for ALK was not reached (95% CI: 44-NR) in trials vs. 77 months (95%CI: 39-NR) in SOC (HR 0.63, 95%CI: 0.26-1.50, p=0.296), and for KRAS G12C was 21 months (95%CI: 11-38) in trials vs. 16 months (95% CI: 9-22) in SOC (HR 1.1, 95%CI: 0.61-1.88, p=0.804).

Conclusions: Patients with oncogene-driven NSCLC enrolled in clinical trials have longer overall survival than those treated with SOC, even after adjusting for trial eligibility confounders.

MA06.07 Benchmarking CT Foundation Models for Survival Prediction in NSCLC Patients

B. Guirges[1], M. Favali[1,2], L. Provenzano[1,2], R. Romanò[2], A. Ferrarin[1], C.M. Licciardello[1], F. Corso[2], L. Invernizzi[2], A. Zec[1,2], L. Lerma[1], V. Peppoloni[2], C. Giangregorio[1], A. Pedrocchi[1], C. Silvestri[2], V. Bartolomeo[2], L. Mazzeo[1,2], M. Brambilla[2], M. Ganzinelli[2], T. Beninato[2], M. Occhipinti[2], C. Proto[2], G. Lo Russo[2], G. Corrao[2], P. Ambrosini[2], F.M. De Braud[2], M. Meazza Prina[2], M.C. Garassino[3], F. Trovò[1], A. Prelaj[2], V. Miskovic[1,2]
[1]Politecnico di Milano, Milano/IT ,[2]Fondazione IRCCS Istituto Nazionale dei Tumori, Milano/IT ,[3]University of Chicago Medical Center, Chicago/IL/USA

Introduction: Radiomic features extracted from Computed Tomography (CT) images have shown promise in capturing tumour prognostic characteristics. Despite PyRadiomics being a state-of-the-art method for this task, foundation models (FMs) showed promising results for feature extraction. This study investigates the use of FMs, comparing their performance with PyRadiomics for extracting CT features to develop robust prognostic signatures for NSCLC patients.

Methods: We analysed 553 CT scans with corresponding lesion segmentations from publicly available TCIA datasets (NSCLC Radiomics and NSCLC Radiogenomics). For each patient, we predicted 24-month survival status (classification, OS-24) and conducted a survival analysis. Features were extracted using 5 methods within two approaches: FMs (Merlin, Google CT, FMCIB, CT-FM; respectively pre-trained on about: 15.000, 600.000, 30.000, and 140.000 CTs), and PyRadiomics. All the FMs, except FMCIB, used the full 3D scan as input, while FMCIB used a portion of the CT containing the main lesion. PyRadiomics features were extracted from the main lesion segmented by an expert radiologist. We relied on standard pre-processing Machine Learning pipelines for data preparation. We trained our method over 443 CTs, and tested it over an independent set of 110 CTs (20% of the total, never seen by the model). Performance was evaluated using Area Under the Curve (AUC) scores for classification and Concordance Index (C-Index) for survival analysis.

Results: In our analysis, Google CT FM achieved the best results in predicting OS-24 (AUC 0.74, 95% CI [0.64, 0.83]), and OS (C-index 0.67, 95% CI [0.60, 0.74]). Google CT demonstrated strong generalizability and minimal overfitting, consistently outperforming PyRadiomics.

Conclusions: Google FM demonstrated strong prognostic capabilities in NSCLC, showing robust and consistent performance across both survival prediction and classification tasks. Notably, this approach achieves superior results without requiring tumour segmentations, offering a significant practical advantage over traditional radiomics methods like PyRadiomics, which rely on precise lesion delineation. These procedures can save radiologists time while maintaining diagnostic performance. Our findings suggest that FMs, when pre-trained on large-scale medical imaging datasets, can effectively capture clinically relevant patterns across the entire CT volume, potentially enhancing the development and application of imaging biomarkers in clinical practice, and allowing the use of small datasets thanks to the reduced risk of overfitting.

MA06.08 Is Weight-Based Pembrolizumab Dosing as Effective as Standard Fixed Dose in Advanced Nsclc?

A. Raphael[1,2], E. Shachar[2,3]
[1]Davidoff Cancer Center, Rabin Medical Center, Petach-Tikva/IL ,[2]Tel-Aviv University, Tel-Aviv/IL ,[3]Tel-Aviv Sourasky Medical Center, Tel-Aviv/IL

Introduction: Immunotherapy has significantly advanced the treatment of patients diagnosed with non-small cell lung cancer (NSCLC). Pembrolizumab was initially studied at doses of 2 mg/kg and was ultimately adopted at a fixed dose of 200 mg every 3 weeks. This strategy was based on pharmacokinetic modeling and clinical trial data demonstrating efficacy and safety across cancer types. The fixed dose was intended to simplify administration and ensure consistent drug exposure. However, it was derived from higher-than-average body weights in U.S. trials, without accounting for lower weights in other regions, among women and individuals with advanced disease, who often experience weight loss. In 2022, Clalit Health Services—the largest health fund in Israel, covering ~50% of the population—adopted weight-based reimbursement for pembrolizumab. The policy was approved and supported by emerging evidence from studies suggesting that lower doses remain effective. Additionally, PD-1 receptor saturation occurs even at relatively low concentrations. This policy unintentionally created a quasi-random division in the population, enabling a real-world comparison of dosing strategies. This study evaluates the efficacy and safety of fixed versus weight-based pembrolizumab.

Methods: We conducted a retrospective cohort study of individuals with advanced NSCLC receiving first-line pembrolizumab, either as monotherapy or in combination with platinum-based chemotherapy. Participants were categorized based on dosing strategy: weight-based (2 mg/kg every 3 weeks) or fixed (200 mg every 3 weeks). Collected variables included age, sex, smoking history, histological subtype, PD-L1 tumor proportion score (TPS), ECOG performance status, body mass index (BMI), and immune-related adverse events (irAEs). Overall survival (OS) was assessed using Kaplan-Meier estimates, with multivariable Cox regression to adjust for relevant clinical factors.

Results: Among 414 individuals, 337 (81.6%) received fixed-dose and 76 (18.4%) weight-based pembrolizumab. Treatment regimens were comparable. A non-significant trend toward improved OS was observed in the weight-based group (p = 0.056). The incidence of irAEs did not differ significantly between groups (p = 0.83), nor did OS among those who experienced irAEs (p = 0.53).

Conclusions: Weight-based dosing of pembrolizumab showed similar efficacy and safety to fixed dosing in this real-world cohort. These findings align with accumulating evidence in recent years suggesting that lower doses may be sufficient for therapeutic effect. Given the potential for substantial cost savings, weight-based dosing may be a viable and sustainable strategy. Prospective studies are needed to confirm these results and inform policy and clinical practice.

MA06.09 Assessing the Impact of Project ASCENT, a Multi-Level Lung Cancer Screening Intervention Targeting Hispanic/Latin Individuals

L. Spiegelman[1], F.N.A. Mustafayev[1], S. Bellur[1], C. Thiry[1], D. Jayram[1], T. Santos[1], B. Quintana[1], F. Sabogal[1], A. Willis[1], M. Varena[1], R. Theodore[2], V. Trouillot[2], P. Rios[2], J. Mulroy[2], M. Futrell[3], U. Basu Roy[3], M. Ahluwalia[1]
[1]Miami Cancer Institute (MCI), Miami/FL/USA ,[2]CLT Business Solutions, Homestead/FL/USA ,[3]LUNGevity Foundation, Chicago/IL/USA

Introduction: Despite proven efficacy of lung cancer screening (LCS) using low-density computed tomography (LDCT) in reducing lung cancer mortality, LCS uptake in screening-eligible individuals remains low nationally and in Florida. Hispanic/Latin (H/L) individuals have lower access to LCS due to a combination of structural and socioeconomic barriers, and cultural norms around screening. To bridge these gaps, Miami Cancer Institute (MCI), in partnership with LUNGevity Foundation, launched Project ASCENT, a multi-level LCS program rooted in culturally sensitive patient navigation, education, and community engagement in 2023 in Miami, Florida. MCI serves a diverse community of H/L individuals. This report evaluates the project's impact on systemwide LCS uptake, engagement, and tobacco cessation.

Methods: Project ASCENT is guided by a Lung Cancer Task Force, consisting of members of H/L community organizations and clinicians. We developed community-specific, pertinent education materials, and two Spanish-English bilingual patient navigators (Care Coaches) conducted extensive community engagement. Multi-year internal data on LDCT screening volume, community engagement metrics (number of events attended, event location ZIP code, estimated event reach), and tobacco cessation referral outcomes between 2022 and 2024 were analyzed. LDCT volume metrics were adjusted for demographics and screening center ZIP code and compared against county-specific and overall catchment area demographics using 2020 U.S. Census data.

Results: We analyzed data from multiple sources to evaluate Project ASCENT's impact (Table 1). • Notable increases in total LDCTs were observed system-wide (4,186 vs. 2,867) and among Hispanics (1,804 vs. 1,184) in 2024 vs. 2022. When further stratified by LDCTs performed at sites within Miami-Dade County, the cohort's H/L makeup increased from 58.7% to 61.5% between 2022 and 2024, with notable volume increases in sites within predominantly H/L ZIP codes. • MCI facilitated targeted LCS outreach at one event in 2022, reaching 550 participants, which grew to 20 events, reaching 39,675 South Floridians in 2024. • Tobacco cessation events increased dramatically between 2022-2024 (32 vs. 189), with 64 patients accepting services in 2024 (vs. 10 in 2022).

Conclusions: Our evaluation suggests that a community engagement strategy with culturally sensitive tobacco cessation information can increase LCS and tobacco cessation utilization in H/L community members. Marked improvements in LDCT volume overall and within the H/L population, community engagement, and tobacco cessation referral outcomes were noted since the implementation of Project ASCENT. Future work rooted in targeted patient and primary care provider education and engagement is necessary to further enhance screening uptake and reduce barriers to care.

Table 1: Lung Cancer Screening and Tobacco Metrics, 2022-2024

Metric	2022	2023	2024	Total
Total LDCT Volume (n, %)				
Entire Catchment Area	2,867 (26.8)	3,650 (34.1)	4,186 (39.1)	10,703
Miami Dade County	1,377 (26.9)	1,752 (34.3)	1,985 (38.8)	5,114
Hispanic/Latinx Individuals Who Underwent LDCT (n, % of yearly total)				
Entire Catchment Area	1,184 (41.3)	1,562 (42.8)	1,804 (43.1)	4,550
Miami Dade County	808 (58.7)	1,060 (60.5)	1,221 (61.5)	3,089
Lung Cancer Screening Outreach Events (n)				
Number of Events	1	4	20	25
Estimated Total Reach	550	638	39,675	40863
Completed Tobacco Cessation Events (n)	32	14	189	235
Tobacco Cessation Event Outcomes (n, %)				
Accepted Services	10 (31.3)	1 (7.1)	64 (33.9)	75
Declined	8 (25.0)	2 (14.3)	43 (22.8)	53

Introduction: Tumor grading has been a traditional component of pathologic evaluation and offers guidance to therapy and patient management in many organs. However, there is no consensus on a grading system for invasive squamous cell carcinoma of the lung (SCC), while a few groups have proposed distinct grading systems using their own cohorts. Thus, we sought to establish a globally acceptable grading system for SCC by using international cohorts.

Methods: Adverse histologic features were evaluated in SCC resected at 3 institutions. The histologic features included the extent of keratinization, basaloid features, tumor budding (TB; 2-tiered or 3-tiered classification), size of the smallest tumor nest at the invasive front (SSTN-FRT), nuclear size, mitosis, necrosis, and tumor spreading through airspaces (STAS) along with lymphovascular and pleural invasion. Kaplan Meier analysis and Proportional Hazards Models were used to identify histologic features associated with recurrence-free survival [RFS] and overall survival [OS] in cohort 1 (from institution 1) and cohort 2 (from institutions 2 and 3 combined) independently. Univariable models included age, sex, smoking history, entire tumor size, pathological tumor stage (AJCC 8th), the resection margin status, and surgery type, along with the histologic features. Multivariable models used step-wise regression ($p<0.1$ for inclusion, $p<0.05$ for retention) to identify significant prognostic factors. Histologic features, which were prognostically significant in both cohorts, were used to construct a grading system.

Results: The study cohort consisted of 689 patients with resected SCC. Cohort 1(n=262) was: age 35-89 years [mean=70.2]; female/male: 44%/56%; stage I/II/III: 62%/25%/13%. Cohort 2 (n=427) was: age 42-91 years [mean=69.7], female/male: 11%/89%; stage I/II/III/IV: 41%/32%/26%/1%. Of the histologic features, TB (2-tiered with a cut-off of 10 tumor buds / 0.785mm2, p=0.001 and p=0.006) and STAS ($p<0.001$ and p=0.006) were statistically significant for RFS and OS, respectively, in cohort 1. In cohort 2, TB (p=0.046) and mitosis (p=0.045) were statistically significant for RFS, and SSRT_FRT (p=0.003), TB (p=0.01), and mitosis (p=0.012) were statistically significant for OS. Given that TB was the only histologic feature statistically significant for both RFS and OS across the cohorts, a 2-tiered grading system based on TB was constructed and clearly stratifies the patient outcomes (Figure).

Conclusions: A 2-tiered grading system based on a single parameter, TB, is practical and predictive of patient outcomes. Validation of the grading system in several independent cohorts is underway, and the reproducibility of the grading system will also be assessed to establish the grading system for SCC.

[1]NIH, BETHESDA/MD/USA ,[2]Fox Chase Cancer Center, Philadelphia/PA/USA ,[3]NIH, Frederick/MD/USA ,[4]National Cancer Center Hospital East, Kashiwa/JP ,[5]Hungarian Centre of Excellence for Molecular Medicine,, Szeged/HU

Introduction: Small-cell lung cancer (SCLC), the most aggressive form of lung cancer, is characterized by rapid progression, extensive heterogeneity, and a lack of clinically actionable biomarkers. Existing gene expression-based classifications are confounded by stromal and immune cell signals, limiting precision and reproducibility. These classifications were derived from bulk tumor data, which obscures tumor-intrinsic changes by averaging signals from tumor, stromal, and immune components. Currently, no classification system independently predicts prognosis or treatment response beyond standard clinical factors, such as the presence of liver metastases.

Methods: We hypothesized that chromatin accessibility, as measured by ATAC-seq, could more effectively define SCLC subtypes than gene expression-based classifications by capturing epigenetic differences and differentiation states. We established a biobank of relapsed SCLC patient-derived xenografts (PDXs) and performed ATAC-seq and RNA-seq on 39 metastatic SCLC PDXs. Non-negative matrix factorization was applied to classify tumors based on chromatin accessibility and identify key transcription factors driving each subtype. RNA-seq-derived signatures were validated across bulk and single-cell RNA-seq data from cell lines and patient samples to assess their prognostic and predictive value

Results: Through ATAC-seq on the newly established biobank of relapsed SCLC PDXs, we defined the tumor-intrinsic chromatin landscape of SCLC and identified three distinct subtypes: (i) SCLC-NE, ASCL1/NEUROD1-driven neuroendocrine subtype, (ii) SCLC-IM, Interferon regulatory factor-associated immunogenic subtype, and (iii) SCLC-SL, a novel stem cell-like subtype marked by TEAD/OCT activation. This classification was validated using bulk and single-cell RNA-seq data across over 800 tumors, including 313 newly profiled samples, consistently reproducing the three-subtype structure in both early and advanced disease. Notably, SCLC-SL, representing one-third of all SCLC cases, was the second most prevalent subtype. In metastatic SCLC patients treated with chemotherapy or chemoimmunotherapy, SCLC-SL was associated with significantly worse overall survival (OS) (HR 1.82, 95% CI 1.34-2.47), independent of clinical factors. Among chemoimmunotherapy-treated patients (n=132), SCLC-SL was an independent predictor of poor prognosis (HR 2.22, 95% CI 1.27-3.89), alongside known adverse factors such as brain metastases, liver metastases, and elevated serum lactate dehydrogenase levels.

Conclusions: This study establishes a clinically actionable chromatin-based classification for SCLC, identifying a novel stem-like subtype associated with poor prognosis and chemoimmunotherapy resistance. Our classification outperforms prior systems (Gay et al., 2021; Nabet et al., 2024) in multivariate analyses, representing the first reproducible prognostic and predictive biomarker in SCLC.

MA07.03 Morphological Implication of Invasive Lung Adenocarcinoma -Analysis Employing AI Method Based on Noguchi's Classification-

H. Kawaii[1], Y. Yatabe[2], A. Yoshizawa[3], Y. Sakai[4], K. Yamashita[5], K. Hotta[5], M. Noguchi[6,7], D. Matsubara[1]
[1]University of Tsukuba, Tsukuba, Ibaraki/JP ,[2]National Cancer Center Hospital, Tsukiji, Tokyo/JP ,[3]Nara Medical University, Kashihara, Nara/JP ,[4]Kansai Medical University Center, Moriguchi, Osaka/JP ,[5]Meijo University, Nagoya, Aichi/JP ,[6]Shonan-Kamakura General Hospital, Fujisawa, Kanagawa/JP ,[7]Narita Tomisato Tokushukai Hospital, Narita, Chiba/JP

Introduction: The size of invasion in lung adenocarcinoma (LUAD) correlates with patients' prognosis and is necessary to decide pT factor. Based on the WHO classification, invasive areas include non-lepidic tumor cells and fibrosis with active fibroblasts (AFs). The histological heterogeneity of invasion might relate to different prognosis. As invasive areas often show intricate mixture of non-lepidic tumor cells and fibrosis with AFs, and non-invasive areas such as alveolar collapse are frequently entrapped in non-lepidic areas, interobserver variability for the pathological diagnosis of invasion occurs in routine pathological diagnosis. This study aims to establish diagnostic tool utilizing artificial intelligence (AI) and support to decrease interobserver variability in pathological diagnosis of LUAD invasion.

Methods: We collected two sets of LUAD resected at Tsukuba University Hospital (Japan). First cohort included 35 cases (2cm or less in diameter) resected from 2007 to 2013. Second cohort included 191 cases (3cm or less in diameter) resected from 2014 to 2024. First, two pathologists (HK and NM) diagnosed all cases according to Noguchi's classification (Cancer, 1995) and WHO histological classification (5th Edition, 2021). Histologically, non-lepidic areas in first cohort were divided into 'non-lepidic tumor cells' (type D-F of Noguchi's classification, solid, acinar and papillary type, and micropapillary type of WHO classification) and 'fibrosis and alveolar collapse' (type C of Noguchi's classification). Since we could easily detect the fibrosis and alveolar collapse by elastic fiber staining, we scanned elastic fiber-stained histological slides by Nano Zoomer (Hamamatsu Photonics, Japan) and whole slide images (WSIs) were annotated by ASAP (Automated Slide Analysis Platform, https://computationalpathologygroup.github.io/ASAP/). We extracted small-sized patches from annotation and divided them into training, validation and test datasets for supervised learning using ResNet50 models. Then we let the trained AI to judge whole non-lepidic areas of second cohort to verify how this AI analyzed histologically heterogeneous areas. Finally, we checked the relationship between prognostic information and AI analysis.

Results: The AI trained based on pathologists' annotation of first cohort achieved 86.2% test accuracy for 'non-lepidic tumor cells' and 92.2% test accuracy for 'fibrosis and alveolar collapse'. After this trained AI analyzed whole non-lepidic region of second cohort (n=191), two pathologists (HK and MN) reviewed the original histology of analyzed cases and compared to the AI's analysis. This AI tended to judge the histologically heterogeneous areas mixed with non-lepidic tumor cells and fibrosis with AFs as 'fibrosis and alveolar collapse' based on the existence of collagenous fiber proliferation. In pT1 cases (n=136), high ratio of 'non-lepidic tumor cells' (>50%) groups showed poor prognosis in 5-years disease-free survival (DFS) rate (76.3% vs 93.3%, p=0.005) and in high ratio of 'non-lepidic tumor cells' groups, central distribution of 'fibrosis and alveolar collapse' was poor prognostic factor in 5-years DFS rate (n=76, 50.0% vs 83.3%, p=0.009).

Conclusions: Utilizing elastic fiber-stained histological slides, we developed an AI engine to distinguish 'non-lepidic tumor cells' and 'fibrosis and alveolar collapse'. We found several prognostic factors based on AI analysis for whole non-lepidic areas, suggesting the possibility of AI-based prognostic criteria of invasive LUAD with low interobserver variability.

MA07.04 Integration of a Molecular Prognostic Classifier Enhances Conventional Staging of Lung Adenocarcinoma

H. Abolfathi, M. Maranda-Robitaille, K-A. Pellerin, V. Saavedra Armero, N. Gaudreault, D.K. Boudreau, M. Orain, P. Desmeules, A. Gagné, F.C. Lamaze, Y. Bossé, P. Joubert
Institut Universitaire de Cardiologie et de Pneumologie de Québec, Laval University, Quebec City/QC/CA

Introduction: The International Association for the Study of Lung Cancer (IASLC) recently released the 9th edition of the lung cancer staging system. Although this edition introduced a few updates compared to the previous edition, it underscored the necessity of integrating novel non-anatomic prognostic factors in future revisions. This study aims to evaluate the incorporation of a molecular prognostic classifier into the conventional staging system, assessing its potential to improve the prediction of overall survival in patients with lung adenocarcinoma (LUAD).

Methods: We included 502 stage I to III LUAD patients who underwent lung cancer resection at IUCPQ-Université Laval, Canada between 2006 and 2021. Survival time was defined as the time from surgical resection to death or censoring at 5 years. The least absolute shrinkage and selection operator (LASSO) was performed to identify the most prognostically relevant genes among 62,700 gene transcripts analysed using bulk RNA sequencing. A molecular risk score was calculated for each patient as a weighted sum of the selected gene expression levels. Patients were subsequently stratified into low-, intermediate-, and high-risk groups based on risk scores. These classifications were integrated into the 9th edition TNM staging (from stage IA1 to IIIC) to create a novel staging system, the TNMEx (where Ex represents gene expression). High-risk patients were up-staged by one level, low-risk patients were down-staged by one level, and intermediate-risk patients remained in their original stage. To evaluate survival prediction and model performance, we calculated the hazard ratio (HR), concordance index (C-index), the area under the curve (AUC), chi-square value, and Akaike information criterion (AIC) for the 8th, 9th edition, and TNMEx staging systems.

Results: We identified 30 predictive genes, which were then integrated into the 9th edition TNM staging to create the novel TNMEx staging. Overall, 67% of patients were reclassified, with most being up-staged to more advanced disease stages due to gene expression data. The final distribution with TNMEx staging was 310, 125, and 67 patients in stages I, II, and III, respectively. The TNMEx staging demonstrated improved predictive ability, with a higher HR (4.3, 95% CI: 3.8-4.9, p = 3.17e-12), and chi-square value (280) compared to the 9th edition (HR = 3.2, 95% CI: 2.6-3.9, p = 4.37e-09; chi-square 80). The TNMEx staging exhibited superior prognostic performance with a C-index of 0.75 (p=7.1e-06), an AUC of 0.77 (p = 1.07e-05), and an AIC of 1097 (ΔAIC=33), compared to the 9th edition with a C-index of 0.64, AUC of 0.68, and AIC of 1130. While the 8th and 9th editions showed no significant improvement in prognostic performance, with a C-index of 0.62 (p = 0.45), AUC of 0.67 (p = 0.29), and AIC score of 1130 (ΔAIC=0) in the 8th edition, the TNMEx system demonstrated a significant enhancement in survival prediction.

Conclusions: The TNMEx staging system was associated with improved prediction of overall survival compared to conventional TNM staging. The integration of a molecular prognostic classifier into the conventional staging system may lead to the enhanced identification of high-risk patients, survival predictions, and treatment decisions.

MA07 NEW PERSPECTIVES IN PATHOLOGY BIOMARKERS
TUESDAY, SEPTEMBER 9, 2025 - 11:30 - 12:45

MA07.05 Lung Cancer With Spread of Tumor Through Air Spaces: Transcriptomic Biosignature of Primary Tumors and Expression Analysis Airway Tumor Clusters

W.S. Brandt, A. Mabry, S. Sankararaman, D. Dev, A.N. Wein, J. Weber, R. Govindan
Washington University St. Louis, St Louis/MO/USA

Introduction: Objective: Up to 40% of resected lung cancer is found to have spread of tumor through air spaces (STAS), a pathological finding associated with poor survival and increased recurrence. However, little is known about genomic and transcriptomic differences in primary tumors with STAS (SP) and without STAS (SN) or expression profiles of the cancer cells within the airway themselves (tumors nests [TN]).

Methods: Methods: To address this knowledge gap, we compared (a) genomic differences between SP and SN tumors, (b) transcriptomic differences between SP and SN tumors, and (c) transcriptomic differences between matched SP tumors and TNs. Extraction of DNA and RNA from fresh frozen tumors was performed for DNA and RNA sequencing. Whole exome sequencing (WES) was performed using 100X depth in SN versus SP tumors matched to normal lung (50X). RNA sequencing was performed using the SigmaPlex kit. RNA from SP and SN tumors was evaluated after normalization using the DESeq2 package in R. Expression differences between SP and the corresponding TNs from the same primary tumor were compared by creating two unique tissue microarrays (TMA) containing 20 cores of SP tumors and 20 cores of TNs from the SP tumors. Slides were created, stained with histologic & eosin stain (H&E), and run on the Visium 10X genomics transcriptomic analysis platform. Genes were considered differentially expressed if they had a false-discovery ratio p-value <0.05 and fold change > 1. Pathway analysis was performed using the GSEA platform and MDSigB Hallmark pathway analysis.

Results: Results: Comparison between 11 SP versus 21 SN tumor was performed for SP vs SN DNA and RNA analysis. (A) WES revealed two genes were significantly differentially altered between groups MOV10L1 (36.4% SP versus 4.72% SN, p=0.04) and CACNA1A (36.4% SP versus 4.72% SN, p=0.04). There was no significant difference in major oncologic drivers including KRAS, EGFR, ALK, TP53, or RET mutation frequency between groups. (B) RNA expression analysis revealed SP tumors had 154 of 19,040 protein-coding genes differentially expressed. Pathway analysis revealed these genes had increased expression of UV response-related genes. (C) Spatial transcriptomic analysis of SP versus matched TNs consisted of 14 adenocarcinomas and 2 squamous cell lung cancers. SP tumors revealed 472 of 15,045 (3.13%) differentially expressed genes in TN versus SP including MMP19, COL3A1, COL1A2, and CDKN2A (Figure 1). Of these 472 genes, there were six differentially expressed pathways in TNs including genes involved in E2F targets, G2-M Checkpoint, Epithelial to Mesenchymal Transition (EMT), and mitotic spindle formation (Table 1).

Conclusions: Conclusions: This preliminary analysis demonstrates unique transcriptomic differences in SP and SN tumors. TNs themselves may represent a more aggressive subset of the primary tumors with increased expression of EMT and DNA repair pathway genes, which may allow them to survive in the airway more readily. If validated, an RNA biosignature could help predict SP tumors prior to resection and potential targeted therapies for STAS could be evaluated in this subpopulation of patients with aggressive lung cancer.

Keywords: Spread of Tumor through Air Spaces, Molecular Pathology, Biosignature

MA07.06 Characterization of Protein Arginine Methyltransferase 5 (PRMT5) Expression in Methylthioadenosine Phosphorylase (MTAP) Deleted NSCLC

R. Hsu[1], S. Deshmukh[2], S. Wu[2], J. Xiu[2], Z. Hao[3], C. Kim[4], A. Vanderwalde[2], P.C. Ma[5], B. Halmos[6], J.J. Nieva[1]
[1]University of Southern California, Los Angeles/CA/USA ,[2]Caris Life Sciences, Phoenix/AZ/USA ,[3]University of Kentucky, Lexington/KY/USA ,[4]Georgetown University, Washington/DC/USA ,[5]Penn State Cancer Institute, Hershey/PA/USA ,[6]Montefiore Einstein Comprehensive Cancer Center, Bronx/NY/USA

Introduction: PRMT5 is a lethal target for cancers with deletion of MTAP gene. As there are PRMT5 inhibitors in development for MTAP deleted (MTAP-del) solid tumors, we wanted to evaluate PRMT5 high expressors and MTAP-del non-small cell lung cancer (NSCLC).

Methods: NSCLC samples were analyzed via NGS (592-gene panel, NextSeq; WES/WTS, NovaSeq; Caris Life Sciences, Phoenix, AZ). PRMT5 high (H) vs PRMT5 not high (NH) was defined as top quartile vs lowest to 3rd quartile of RNA expression, respectively. Real-world overall survival (OS) was calculated from tissue collection or treatment to last contact using Kaplan-Meier estimates. Statistical significance was assessed using chi-square and Mann-Whitney U with multiple comparison adjustments (q<0.05).

Results: Of 39,124 tumors, 6837 (17.4%) were MTAP-del. There was a greater proportion of MTAP-del tumors in PRMT5-H (34.2% vs 25.7%) versus PRMT5-NH. There were more MTAP-del tumors in PRMT5-H adenocarcinoma (33.5% vs 24.6%) and in squamous cell carcinoma (SCC) (35% vs 29%). MTAP-del tumors had worse median OS (16.4 vs 20.5 m, p<0.0001) versus MTAP-not deleted (-ND); this was seen in adenocarcinoma (18.9 vs 25.2 m, p <0.0001) but not in SCC (p=0.8). The combination of PRMT5-H/MTAP-del tumors had worse mOS (12.7 vs 22.1 m) versus PRMT5-NH/MTAP-ND (p<0.0001). MTAP-del had lower mutations in RB1 and CDKN2A versus MTAP-ND in both PRMT5-H and PRMT5-NH while TP53 and RASA1 were only lower in PRMT5-H/MTAP-del and KRAS in PRMT5-NH/MTAP-del. EGFR, APC, STK11, KEAP1 and SMARCA4 mutations were higher in both PRMT5-H/MTAP-del and PRMT5-NH/MTAP-del (Table). PRMT5-H/MTAP-del and PRMT5-NH/MTAP-del had lower prevalence of PD-L1+ (q<0.05). MTAP-del had lower infiltration of M1, M2 macrophages, CD8+ T cell, and Tregs in PRMT5-H and -NH tumors (all q<0.05), (Table). PRMT5-H/MTAP-del and PRMT5-NH/MTAP-del had lower IFNγ score (q<0.05). PRMT5-H/MTAP-del tumors treated with immune checkpoint inhibitors (ICI) had worse mOS (13.8 vs 19 m, p<0.0001) versus PRMT5-NH/MTAP-ND. KRAS-mutated PRMT5-H/MTAP-del tumors treated with ICI ahad worse mOS (11.8 vs 21.4 m, p<0.0001). In EGFR-mutated treated with osimertinib and KRAS G12C mutated treated with sotorasib and adagrasib, there was no mOS difference by MTAP-del status though PRMT5-H tumors trended towards worse mOS.

Conclusions: PRMT5-H/MTAP-del tumors had worse mOS, were enriched in EGFR and APC mt and had lower PD-L1+ prevalence. PRMT5-H/MTAP-del tumors had a less robust and inflamed immune microenvironment, and this was reflected in worse mOS to ICI. Combination strategies of PRMT5 inhibition with ICI or targeted therapy may be merited to improve OS in PRMT5-H expressors that are MTAP-deleted.

Table: Prevalence of mutations, PD-L1+, and IFN-gamma score by *PRMT5* expression and MTAP deletion status

	PRMT5 high (H)			*PRMT5* not high (NH)		
	MTAP not deleted	*MTAP* deleted	q-value	*MTAP* not deleted	*MTAP* deleted	q-value
TP53 %	77.75	73.62	0.001	64.13	64.27	0.88
RB1 %	13.22	5.95	<0.0001	9.21	3.94	<0.0001
EGFR %	9.07	11.06	0.03	11.21	14.32	<0.0001
CDKN2A %	12.96	9.35	0.0002	11.42	7.91	<0.0001
APC %	3.2	4.52	0.02	2.37	3.22	0.002
STK11 %	12.91	15.28	0.02	11.8	15.48	<0.0001

Introduction: Amivantamab, an EGFR-MET bispecific antibody, is approved with the tyrosine kinase inhibitor (TKI) lazertinib for first-line EGFR-mutated advanced/metastatic NSCLC, and with chemotherapy after progression on EGFR-TKIs such as osimertinib. Resistance mechanisms to osimertinib are diverse, polyclonal, and include MET alterations (Besse et al. ESMO. 2024), which underscores the importance of administering the most effective treatment first. MET positivity (MET+ [MET 3+ staining on ≥25% of tumor cells]) was identified as a potential biomarker for response to amivantamab-lazertinib after disease progression on osimertinib in the CHRYSALIS-2 study (Besse et al. ASCO. 2023). CHRYSALIS-2 (NCT04077463) Cohorts E and F aimed to prospectively validate this potential biomarker among amivantamab-lazertinib and amivantamab monotherapy recipients, respectively.

Methods: Cohorts E and F enrolled participants with EGFR Ex19del or L858R-mutated advanced NSCLC with tumor tissue collected for immunohistochemistry (IHC) staining post-progression on osimertinib. Prior chemotherapy was exclusionary. Participants were randomized 1:1 to receive standard-dose intravenous amivantamab with oral lazertinib (Cohort E) or amivantamab monotherapy (Cohort F). The Bayesian posterior probability of investigator-assessed ORR for both the MET+ group (ORR >35%) and the MET- group (ORR <20%) should be >85% for acceptance. Interim analysis was prespecified when ~55 response-evaluable participants with IHC data were in each cohort.

Results: As of 11-Jul-2024, 68 and 64 participants from Cohorts E and F, respectively, were response-evaluable and had IHC data (median follow-up of 4.5 months). Of these, 27 (40%) in Cohort E and 20 (31%) in Cohort F were MET+. Most participants in Cohort E were White (60%), while most in Cohort F were Asian (59%).

ORR (confirmed responses) in Cohort E was 30% (95% CI, 14-50) for MET+ and 15% (95% CI, 6-29) for MET- (Table). ORRs in Cohort F were 30% (95% CI, 12-54) and 11% (95% CI, 4-25), respectively. While ORRs were numerically higher in the MET+ groups, prespecified validation criteria were not met. Median progression-free survival (PFS) was 6.9 months (95% CI, 4.4-NE) for MET+ and 4.3 months (95% CI, 2.8-8.1) for MET- in Cohort E. In Cohort F, median PFS was 5.6 months (95% CI, 2.8-NE) and 4.4 months (95% CI, 1.6-NE), respectively.

Conclusions: In this analysis, IHC MET+ was not validated as a biomarker for response to amivantamab-lazertinib or amivantamab monotherapy among participants with EGFR-mutated NSCLC after osimertinib treatment. Nevertheless, amivantamab alone or with other agents is efficacious for advanced/metastatic NSCLC. Additional results will be reported at the meeting.

Table. Efficacy Endpoints

Endpoint	Amivantamab-lazertinib (Cohort E)		Amivantamab monotherapy (Cohort F)	
	MET+ n=27	MET⁻ n=41	MET+ n=20	MET⁻ n=44
ORR, % (95% CI)[a]	30 (14-50)	15 (6-29)	30 (12-54)	11 (4-25)
Median PFS, months (95% CI)[b]	6.9 (4.4-NE)	4.3 (2.8-8.1)	5.6 (2.8-NE)	4.4 (1.6-NE)

CI, confidence interval; NE, not estimable; ORR, objective response rate.
[a]In confirmed responders.
[b]Note that median follow-up for this analysis was short, at 4.5 months.

MA07.08 MFAP4+ Pericytes Promote Tc17-Mediated Pneumonitis Induced by the Combination of Radiotherapy & Immunotherapy

Y. Lin[1], J. Xiong[1], Z. Dong[1], X. Bai[1]
[1]Southern Medical University, Guang Zhou/CN

Introduction: Radiotherapy's immunogenic effects make it an attractive partner for immunotherapy. However, combined radio-immunotherapy is associated with significant adverse events, including pneumonitis, a frequent ≥Grade 3 toxicity. Early identification of susceptible patients and mitigation strategies are urgently needed.

Methods: Peripheral blood was prospectively collected from patients undergoing radio-immunotherapy. Pneumonitis was assessed clinically and by CT. Single-cell secretome profiling was performed to identify key T cell populations, validated using a murine radio-immunotherapy-induced pneumonitis model. Cell-cell interaction maps were generated from murine lungs post-radio-immunotherapy, and candidate target inhibitors were used to identify factors driving Tc17 recruitment. Single-cell multi-omics and in vitro/in vivo experiments were combined to investigate underlying mechanisms.

Results: Single-cell secretome profiling and the murine model confirmed Tc17 cells as key effector cells in radio-immunotherapy-associated pneumonitis, with radiotherapy-mediated lung recruitment being critical. Cell communication maps identified pericytes as the most significant cell type interacting with Tc17 cells in the irradiated lung. PDGFRβ inhibition to deplete pericytes reduced Tc17 infiltration and attenuated pneumonitis. Integrated RNA sequencing and single-cell transcriptomics identified MFAP4 as a specific and evolutionarily conserved pericyte marker. Enrichment analysis revealed involvement of MFAP4+ pericytes in pro-inflammatory responses and matrix degradation. In vitro co-culture further demonstrated that MFAP4+ pericytes can upregulate MMP2/MMP9 in the microenvironment, leading to matrix softening, promotion of an inflammatory microenvironment, Tc17 activation, and exacerbated inflammation. Notably, stiffness measurements confirmed lung softening in irradiated mice.

Conclusions: Tc17 cells are key effectors in radio-immunotherapy-related pneumonitis. MFAP4+ pericytes, by mediating their recruitment and activation, contribute to pneumonitis development. Targeting MFAP4+ pericytes may be a novel strategy to mitigate radio-immunotherapy-induced pneumonitis.

MA07.09 Three-Year Survival Update and Biomarker Analysis of Neoadjuvant Chemoimmunotherapy in Potentially Resectable Stage IIIA/IIIB NSCLC

K. Ma, C. Sun, X. Wang, Y. Xu, S. Qiu
First Hospital of Jilin University, Changchun/CN

Introduction: Accurate biomarker identification for stratifying patients undergoing surgery following neoadjuvant chemoimmunotherapy remains a pivotal challenge, requiring further exploration.

Methods: This study utilized a prospective, single-arm, phase II clinical trial (NCT04326153) to evaluate treatment-naïve patients with "potentially resectable" stage IIIA/IIIB NSCLC. Patients received neoadjuvant therapy comprising Sintilimab, nab-paclitaxel, and carboplatin for 2-3 cycles, followed by surgical resection and systematic nodal dissection. Adjuvant therapy included nab-paclitaxel, carboplatin, with optional Sintilimab as maintenance treatment. The primary endpoint—2-year disease-free survival (DFS) rate—has been previously reported. This analysis updates 3-year survival outcomes while examining tertiary lymphoid structures (TLS) as a biomarker for long-term prognosis. TLS maturation and abundance were assessed using immunohistochemical and multiplex immunofluorescence (CD3, CD20, CD21, BCL-6). TLS maturation was categorized into three stages: early, primary follicle-like, and secondary follicle-like TLS. TLS abundance scores ranged from 0 to 3.

Results: After a median follow-up of 51.7 months (data cutoff: August 2024), 36-month event-free survival (EFS) and overall survival (OS) rates for the intent-to-treat (ITT) population were 60% and 76.7%, respectively(Fig1AB). Notably, patients with TLS abundance scores of 3 achieved significantly superior 3-year DFS rates compared to those with scores of 2 (100% vs. 41.67%, $p<0.05$)(Fig1D) and also demonstrated higher pathological complete response (pCR) rates (75% vs. 17%, $p=0.019$)(Fig1EF). In patients with PD-L1 expression <1%, those with TLS abundance scores of 3 experienced no recurrence, whereas 83.33% of patients with scores of 2 experienced disease recurrence(Fig1C). Regardless of maintenance immunotherapy, patients with TLS abundance scores of 3 showed no disease progression. TLS abundance emerged as a strong independent predictor of DFS with an impact weight of 0.75.

Conclusions: Neoadjuvant chemoimmunotherapy has significantly improved long-term survival for patients with potentially resectable stage IIIA/IIIB NSCLC. TLS abundance enables precise prognosis stratification and personalized treatment strategies, thereby optimizing outcomes.

Introduction: Sunvozertinib (DZD9008) is a rationally designed, potent, irreversible epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI) for the treatment of non-small cell lung cancer (NSCLC) with EGFR exon 20 insertion mutations (exon20ins). Here we report the updated results of the multinational phase 2 randomized pivotal study (WU-KONG1 Part B, NCT03974022) of sunvozertinib in platinum pretreated NSCLC with EGFR exon20ins. The results of the study support its NDA application currently under US FDA review.

Methods: NSCLC patients with EGFR exon20ins with at least one line of prior systemic therapy were enrolled into WU-KONG1B study. Based on earlier studies, patients were initially randomized into 200 mg or 300 mg once daily (QD). A planned interim analysis was performed to determine the optimal dosage to complete the study. The primary and key secondary endpoints were objective response rate (ORR) and duration of response (DoR), as assessed by Blinded Independent Central Review (BICR) per RECIST 1.1. Safety was assessed by investigators and graded per CTCAE 5.0.

Results: As of December 2, 2024, a total of 184 eligible patients were randomized into 200 mg (N=91) and 300 mg (N=93) dose cohorts, respectively. Among them, 85 and 89 patients were included in the efficacy analysis from each cohort, 45.4% of patients were ≥65 years old, and 60.9% of patients were female. More than 47 different EGFR exon20ins subtypes were enrolled, and 24.1% of patients had brain metastasis at baseline. All efficacy evaluable patients were treated with platinum-based chemotherapy, and 13.8% had prior amivantamab treatment. The confirmed ORRs, as evaluated by BICR, were 45.9% (97.5% CI: 33.6%, 58.5%) and 47.2% (97.5% CI: 35.1%, 59.5%), respectively, for 200 mg and 300 mg cohorts. The study met its primary endpoint with statistical significance (p <0.0001). At 200 mg and 300 mg, the median DoR were 11.1 months (95% CI: 8.2, NE) and 13.8 months (95% CI: 8.3, NE), respectively. Patients with baseline brain metastasis and prior amivantamab treatment benefited more from 300 mg dose cohort, with higher confirmed ORRs at 300 mg (52.4% and 41.7%) compared to those of 200 mg (28.6% and 25%). The safety profile of sunvozertinib was similar to what has been previously reported. At both dose levels, the most common grade 3 or above drug-related treatment-emergent adverse events (TEAEs) included diarrhea, blood creatine phosphokinase increased and anemia. TEAEs were clinically manageable. Drug-related TEAEs leading to treatment discontinuation were 4.4% (200 mg) and 7.5% (300 mg), respectively. No drug-related TEAEs with fatal outcome were reported at both dose levels.

Conclusions: Consistent with earlier report, significant antitumor efficacy was confirmed in the study with longer follow-up time. No new safety findings have been reported. Overall, 300 mg once daily showed more favorable clinical outcomes, especially for patients with prior amivantamab treatment or baseline brain metastasis. Detailed data will be presented at the conference.

Introduction: While amivantamab (ami) is approved for the first and second-line treatment of EGFR ex20ins+ NSCLC, a significant unmet need remains for pts intolerant to or progressing on or after ami. Zipalertinib (CLN-081, TAS6417) is a novel EGFR TKI with promising clinical activity and manageable safety as reported previously (Piotrowska et al, JCO 2023). We present updated data from the phase 2b REZILIENT1 study with a focus on patients with EGFR ex20ins mutant NSCLC previously treated with amivantamab.

Methods: Pts with prior treatment including ami were enrolled. Zipalertinib was orally administered at 100 mg BID. Tumor response was assessed by independent central review per RECIST v1.1.

Results: As of the 10 Dec 2024 data cut-off (DCO), 83 pts with prior ami were enrolled. Pts had a median age of 62 years (31-85) and had received a median of 2 (1-7) prior treatment lines, including chemotherapy in 79 (95.2%) pts, anti-PD(L)1 in 38 (45.8%), ex20ins-specific TKIs in 33 (39.8%), and common EGFR TKIs in 23 (27.7%). Treatment-related AEs (TRAEs) occurring in > 10% of pts were paronychia (36.1%), rash (30.1%), dermatitis acneiform (20.5%), anemia (20.5%) nausea (16.9%), dry skin (15.7%), pruritus (14.5%), stomatitis (13.3%), and diarrhea (13.3%). Grade > 3 TRAEs reported in > 2 pts included anemia in 6 (7.2%) and pneumonitis, rash and platelet count decrease each in 3 pts (3.6%). TRAEs led to dose reduction or discontinuation in 7 pts (8.4%) each. At the current DCO, 30 pts with prior ami but no other ex20ins targeted therapy (ami alone) and 21 pts with prior ami and other ex20ins targeted therapy (ami plus) were evaluable for response with at least ~8 months follow-up (total 51 pts). As shown in the table, the ORR in ami only pts was 30% (95% CI: 14.7, 49.4) and disease control rate (CR + PR + SD) was 96.7%. Median DOR and PFS were 14.7 (95% CI: 4.2, NE) and 7.6 (95% CI: 5.4, 9.8) months, respectively. 12-month overall survival rate was 66.1%. Mature efficacy data, including at least 9 months follow up for all 83 pts will be presented.

	ORR (%, 95% CI)	DOR (%, 95% CI)	PFS (m,95% CI)	OS rate @12 month
Ami alone	30.0 (14.7, 49.4)	14.7 (4.2, NE)	7.6 (5.4, 9.8)	66.1%
Ami plus	14.3 (3.0, 36.3)	4.2 (3.9, NE)	5.2 (3.2, 11.5)	51.1%
Overall	23.5 (12.8, 37.5)	8.5 (4.2, 14.8)	7.3 (5.3, 9.7)	59.8%

Conclusions: Zipalertinib demonstrated clinically meaningful efficacy with a manageable safety profile in pts with exon20ins NSCLC who have received prior chemotherapy and prior amivantamab, reflecting a clinically-relevant patient population for which there are currently no approved therapies.

Introduction: Intravenous amivantamab plus chemotherapy (carboplatin-pemetrexed)is approved for first-line treatment of patients with EGFR exon 20 insertion(Ex20ins)-mutated advanced non-small cell lung cancer (NSCLC), based on the resultsof the PAPILLON study. In PAPILLON (median follow-up, 14.9 months), amivantamab-chemotherapydemonstrated a median progression-free survival (PFS) of 11.4 months (95% CI,9.8-13.7) and an investigator-assessed objective response rate (ORR) of 66%. Inthe PALOMA-3 study, subcutaneous amivantamab administered every 2 weeks demonstratednoninferior pharmacokinetics and efficacy versus intravenous amivantamab, with fewerinfusion-related reactions, shorter administration time

(<5 minutes), and higher patient convenience. PALOMA-2 (NCT05498428) is a bridging study evaluating the efficacy, pharmacokinetics, and safetyof subcutaneous amivantamab in various EGFR-mutated advanced NSCLCsettings.

Methods: Cohort2 enrolled participants with treatment-naïve EGFR Ex20ins-mutatedadvanced NSCLC. Subcutaneousamivantamab (co-formulated with hyaluronidase; rHuPH20) was administeredas an abdominal injection with an every 3 weeks (Q3W) dosing regimen of 1600 mg(≥80 kg: 2240 mg) on Cycle 1 Day 1, then 2400 mg

(≥80 kg: 3360 mg) on Days 8 and 15 of Cycle 1, and Q3W thereafter. Carboplatin wasadministered Q3W for up to 4 cycles, and pemetrexed was administered Q3W untildisease progression. The primary endpoint was investigator-assessed ORR perRECIST v1.1.

Results: As of the data cut off (24 October 2024), 66 participantshave received subcutaneous amivantamab Q3W, with the cohort fully enrolled.Median age was

63 years, 52% of participants were male, and 56% were Asian. At a medianfollow-up of 10.4 months, the median treatment duration was 9.3 months. At datacutoff, 37 (56%) participants remained on treatment.Investigator-assessed ORR was 76% (confirmedresponders, 71%) and independent central review-assessed ORR was 77% (confirmedresponders, 67%). Responses were rapid, with a median time to response of 6.4 weeks(range, 3.5-21.7). Median duration of response was 10.6 months (95% CI, 8.3-notestimable [NE]). Among confirmed responders, 66% (31/47) had an ongoingresponse. Median PFS was 12.2 months (95% CI, 8.4-NE) while median overallsurvival was NE. Mean (SD) amivantamab concentration on Cycle 2 Day 1 was 439(117) µg/mL (n=41), consistent with historical intravenous amivantamab Q3Wdata.No new safety signals were observed. Most treatment-emergentadverse events (AEs) were EGFR/MET-related or reversible hematologic AEs, with paronychia,hypoalbuminemia, and neutropenia being the most common. Administration-relatedreactions (ARRs) were reported in 4 (6%) participants (none grade ≥3). Discontinuationof amivantamab due to treatment-related AEs was 12%.

Conclusions: Among participants with EGFR Ex20ins-mutatedadvanced NSCLC, first-line treatment with subcutaneous amivantamab Q3W plus chemotherapydemonstrated a response rate and safety profile consistent with historical intravenousamivantamab Q3W data, with a reduced incidence of ARRs.

Introduction: Patients with non-small cell lung cancer (NSCLC) harboring uncommon non-exon 20 insertion (non-ex20ins) epidermal growth factor receptor (EGFR) mutations (EGFRmt), including G719X, S768I, and L861Q among the most prevalent, have a worse prognosis than those with common single/compound EGFRmt. Responses to currently approved EGFR tyrosine kinase inhibitors (TKIs) are variable in these patients, highlighting the need for novel treatment options. Zipalertinib is an oral, highly selective, irreversible EGFR TKI that has demonstrated preliminary clinical activity against ex20ins and preclinical activity against uncommon, non-ex20ins EGFR-mutated NSCLC. Here, we present preliminary efficacy and safety results for zipalertinib in patients with NSCLC with uncommon, non-ex20ins EGFRmt from the ongoing, multicohort, phase 2b REZILIENT2 trial (NCT05967689).

Methods: Eligible patients had locally advanced/metastatic NSCLC, documented single or compound uncommon, non-ex20ins EGFRmt, and any line of prior therapies. Patients received zipalertinib 100 mg orally twice daily until progressive disease or meeting other withdrawal criteria. The primary endpoint was confirmed objective response rate (ORR) per investigator-assessed Response Evaluation Criteria in Solid Tumours (RECIST) v1.1; secondary endpoints included duration of response (DoR), disease control rate (DCR), and safety.

Results: At data cutoff (February 17, 2025), 40 patients were enrolled, with a median age of 66 (range, 47-85) years, 55% were female, and a median of 2 (range, 1-12) prior lines of therapy. The most frequent EGFRmt were G719X (n=20) and L861Q (n=11); three patients had compound mutations. Overall, confirmed ORR was 30% (95% confidence interval [CI]: 16.6, 46.5), with a median DoR of 7.75 months (95% CI: 3.48, not estimable) and a DCR of 70% (95% CI: 53.5, 83.4). For treatment-naïve patients (n=8), ORR was substantially higher (ORR: 62.5%; 95% CI: 24.5, 91.5) compared with patients with ≥1 prior treatment (n=32; ORR: 21.9%; 95% CI: 9.3, 40.0). Safety findings for zipalertinib 100 mg twice daily were similar to previous studies. Treatment-related adverse events (TRAEs) of any grade occurring in ≥30% of patients were paronychia (47.5%), dermatitis acneiform (37.5%), stomatitis (32.5%), and anemia (30.0%). Grade ≥3 TRAEs reported in ≥2 patients were paronychia and anemia (n=2 each). Dose reductions, interruptions, or treatment discontinuations due to AEs occurred in 10 (25.0%), 19 (47.5%), and six (15.0%) patients, respectively.

Conclusions: Zipalertinib demonstrated preliminary clinical efficacy in patients with NSCLC harboring uncommon, non-ex20ins EGFRmt. The safety profile of zipalertinib was manageable, with no new safety signals. Enrollment in this study is ongoing, focusing on previously untreated patients to confirm the observed preliminary clinical efficacy.

Introduction: Non-small cell lung cancer (NSCLC) with epidermal growth factor receptor (EGFR) mutations and brain metastases (BM) is associated with very limited outcomes using current EGFR-tyrosine kinase inhibitors (TKIs) or treatments. Asandeutertinib (TY-9591), a novel EGFR-TKI candidate, has shown outstanding efficacy and manageable safety in the interim analysis derived from the ESAONA-pivotal study.

Methods: ESAONA-pivotal is an open-label, multi-center, randomized phase II study evaluating first-line treatment between asandeutertinib and osimertinib in untreated NSCLC patients with EGFR-sensitive mutations and stable BM. Patients were enrolled and randomized at 1:1 to receive either asandeutertinib (160mg orally, QD) or osimertinib (80mg orally, QD). Randomization was stratified by intracranial lesions (> 3 or ≤3) and mutation type (L858R or 19Del). The primary endpoints were blinded independent central review (BICR)-assessed intracranial objective response (iORR), with the sample size estimated as 220 (conditional approval by China National Medical Products Administration (NMPA) based on the interim analysis) based on effect size of 15%, and intracranial progression free survival (iPFS) per RECIST v1.1, with the sample size of 420 (full approval by China NMPA) assuming a hazards ratio of 0.737 (both at one-side alpha of 0.025 and beta of 0.2). The secondary endpoints included investigator (INV)-assessed iORR and iPFS, ORR, PFS, overall survival (OS), safety.

Results: As the data cut-off date on Feburary 28, 2025, 257 eligible patients were enrolled from 51 centers. In the interim analysis, baseline characteristics were generally balanced across asandeutertinib (n=111) and osimertinib groups (n=113): median ages 61.0/58.0 (range 38-75/39-76) years, male 32.4%/41.6%, non-smoker 74.8%/68.1%, ECOG PS 1 of 90.1%/79.6%, intracranial lesions > 3 of 58.6%/57.5%, EGFR mutation types with L858R/19Del of 45.9%/54.1% in the asandeutertinib group, 47.8%/52.2% in the osimertinib group. All were adenocarcinoma. The confirmed BICR-iORR was significantly improved for asandeutertinib compared to osimertinib (91.9%, 95% CI 85.2-96.2% vs. 76.1%, 95% CI 67.2-83.6%; P=0.001). The confirmed INV-iORR was also significantly higher for asandeutertinib compared to osimertinib (91.0%, 95% CI 84.1-95.6% vs. 75.2%, 95% CI 66.2-82.9%; P=0.002). The confirmed BICR-ORR showed a trend in favor of asandeutertinib compared to osimertinib (84.7%, 95% CI 76.6-90.8% vs. 75.2%, 95% CI 66.2-82.9%; P=0.095). Median iPFS and PFS had not been reached. OS remained immature. Grade ≥ 3 treatment-related adverse events (TRAEs) were reported in 31.5%/15.0% for asandeutertinib vs. osimertinib. In the asandeutertinib group, Grade ≥ 3 TRAEs occurring ≥ 3 times included increased creatine phosphokinase (n=6, 5.4%), prolonged QTcf (n=5, 4.5%), lymphocytopenia (n=3, 2.7%), neutropenia (n=3, 2.7%), leukopenia (n=3, 2.7%), weight loss (n=3, 2.7%), stomatitis (n=3, 2.7%), and rash (n=3, 2.7%). Serious TRAEs occurred in 9.0%/6.2% (asandeutertinib vs. osimertinib). Adverse events of special interest included 7 patients with interstitial lung disease (ILD) and 5 patients with prolonged QTcf in the asandeutertinib group (11/111, 9.9%, one patient experiencing both events), and 2 patients with ILD in the osimertinib group (2/113, 1.8%).

Conclusions: The interim results of ESAONA-pivotal study demonstrated that asandeutertinib pronouncedly improved intracranial efficacy compared to osimertinib with a manageable safety profile. Asandeutertinib is a promising new first-line option for EGFR-mutated NSCLC patients with BM.

MA08.07 OCELOT: A Pan-Canadian Study of Osimertinib for Patients with Treatment Naive Advanced NSCLC with Uncommon EGFR Mutations

D. Breadner[1], G. Liu[2], P. Wheatley-Price[3], I. Menjak[4], Y. Wang[5], J. Rothenstein[6], M. Valdes[7], P. Bains[8], R. Juergens[9], P. Cheema[10], M. Vincent[11]
[1]Verspeeten Family Cancer Centre at Schulich School of Medicine, London/ON/CA ,[2]Princess Margaret Cancer Centre, Toronto/ON/CA ,[3]University of Ottawa and Ottawa Hospital Research Institute, Ottawa/ON/CA ,[4]Odette Cancer Center at Sunnybrook Health Sciences, Toronto/ON/CA ,[5]British Columbia Cancer Agency, Vancouver/BC/CA ,[6]Lakeridge Health, Oshawa/ON/CA ,[7]Grand River Cancer Centre, Kitchener/ON/CA ,[8]Lions Gate Hospital, Vancouver/BC/CA ,[9]Juravinski Cancer Centre, Hamilton/ON/CA ,[10]William Osler Health System, Brampton/ON/CA ,[11]Verspeeten Family Cancer Centre, London/ON/CA

Introduction: Osimertinib is a popular and well tolerated first-line (1L) option for patients with the two 'common' types of epidermal growth factor receptor mutation-positive (EGFR+) advanced non-small-cell lung cancer (aNSCLC), based on the FLAURA study. Uncommon EGFR mutations (non-exon 19 del and L858R) occur in up to 25% of patients; however, the efficacy of osimertinib in this population is not well understood. To date, small prospective studies and retrospective case series have signalled that osimertinib has a role in the treatment of patients with uncommon EGFR mutations.

Methods: This is a multicentered Canadian phase II investigator-initiated study of 1L osimertinib (cohort B) in patients with uncommon activating EGFR mutations (exon 20 insertions are not permitted). Patients with stable and/or treated brain metastasis, and ECOG performance status 0-3 were permitted on study. Patients with compound mutations that included exon 19 del and L858R were not permitted following an early protocol amendment. Patients were not required to have measurable disease by RECIST and imaging reassessments were every 12 weeks. Key endpoints included objective response rate (ORR), progression free survival (PFS), time to treatment failure (TTF) and overall survival (OS). NCT04335292

Results: Ninety-two patients have been accrued to date with a median follow-up of 8.4 months (IQR: 4.1, 16.6), of whom 62 had evaluable disease (16 had inadequate follow-up time, 14 did not have evaluable disease). Deomgraphics: 67% female; 59% Causasian and 25% East Asian; 33% had brain metastasis at enrollment; median age 69 years. Four patients had compound mutations containing a common EGFR variant, and were excluded from subgroup analyses. The most frequent 'uncommon' EGFR mutation was G719X (n=35), followed by L861X (n=24) and S768I (n=18). The confirmed ORR was 45% (95% CI: 33.4-57.5%) and disease control rate (DCR) was 77% (65.6-86.0%). Median PFS was 14.3, and TTF was 14.9 months. Patients with PACC mutations and common-uncommon mutations (containing G719X, L861X, and/or S768I) had a median PFS of 14 and 14.3 months, respectively, and a median TTF of 14.8 and 16.7 months, respectively. Median overall survival was not reached. Two patients discontinued osimertinib because of adverse events without progressive disease, the overall safety and toxicity profile is consistent with published data. **Conclusions:** Osimertinib appears to be highly active and well tolerated in patients EGFR+ aNSCLC harboring uncommon mutations. The OCELOT study supports the use of osimertinib in this population as a standard of care option.

MA09.01 Association of Air Pollution Exposure With Lung Screening Outcomes and Lung Cancer Risk in the Taiwan TALENT Study

R. Meza[1,2], C-H. Chiu[3], C.H. Durney[1], G-C. Chang[4], K. Xu[1], C-J. Yu[5], Y. Chen[1], M. Brauer[2], S. Lam[1], P-C. Yang[5]
[1]BC Cancer Research Institute, Vancouver/BC/CA ,[2]University of British Columbia, Vancouver/BC/CA ,[3]Taipei Medical University, Taipei/TW ,[4]Chung Shan Medical University, Taichung/TW ,[5]National Taiwan University, Taipei/TW

Introduction: Air pollution is associated with increased lung cancer risk, with recent evidence suggesting a role in tumor promotion among people who have never smoked. However, the temporal relationship between exposure and outcome remains unclear. Moreover, as lung cancer screening is being considered for people with other risk factor exposures than smoking, it is critical to assess the impact that air pollution might have on screening outcomes in non-smoking populations.

Methods: We used data from the Taiwan Lung Cancer Screening in Never-Smoker Trial (TALENT) study to assess the association between air pollution PM2.5 exposures and lung cancer screening outcomes and lung cancer risk among people who have never smoked. Participants' residential address at enrollment was geocoded and then used to estimate past 3-year average PM2.5 concentration at the baseline residence. Outcomes studied included 1) having a nodule present at the baseline screen, 2) having a positive screen (TALENT criteria), 3) LungRADS 3 or 4 screening result, 4) LungRADS 4 screening result, 5) lung cancer diagnosis within a year, and 6) advanced lung cancer diagnosis within a year. Logistic regression was used to assess the association between PM2.5 exposure and each outcome, adjusting for relevant covariates (age, sex, COPD, TB, indoor cooking, and family history of lung cancer). Both age and average 3-year PM2.5 exposure were modeled continuously using restricted cubic splines.

Results: Average annual past 3-year PM2.5 exposure ranged from 12.75 to 32.53 µg/m3, with a median of 22.11 among cancer patients and 21.22 among non-cases. PM2.5 exposure was statistically significantly associated with all study outcomes, including lung cancer, with non-linear inverted U-shaped dose responses. For all outcomes, risk increased with PM2.5 at exposure levels from 12 to 20 µg/m3, peaking between 20 and 25 µg/m3 and then decreasing. For lung cancer, increasing age, female sex, and the number of first-degree family members with a history of lung cancer were positively associated with higher risk.

Conclusions: Recent PM2.5 exposure was associated with lung cancer risk and with the risk of having nodules, having a positive screen, and having advanced lung cancer screening results at a baseline screening exam among people who never smoked in Taiwan. These results are consistent with research suggesting a role of air pollution in tumor promotion. Future studies should evaluate the effects of air pollution exposures at different time periods (recent vs distant) on tumor dynamics and lung cancer risk.

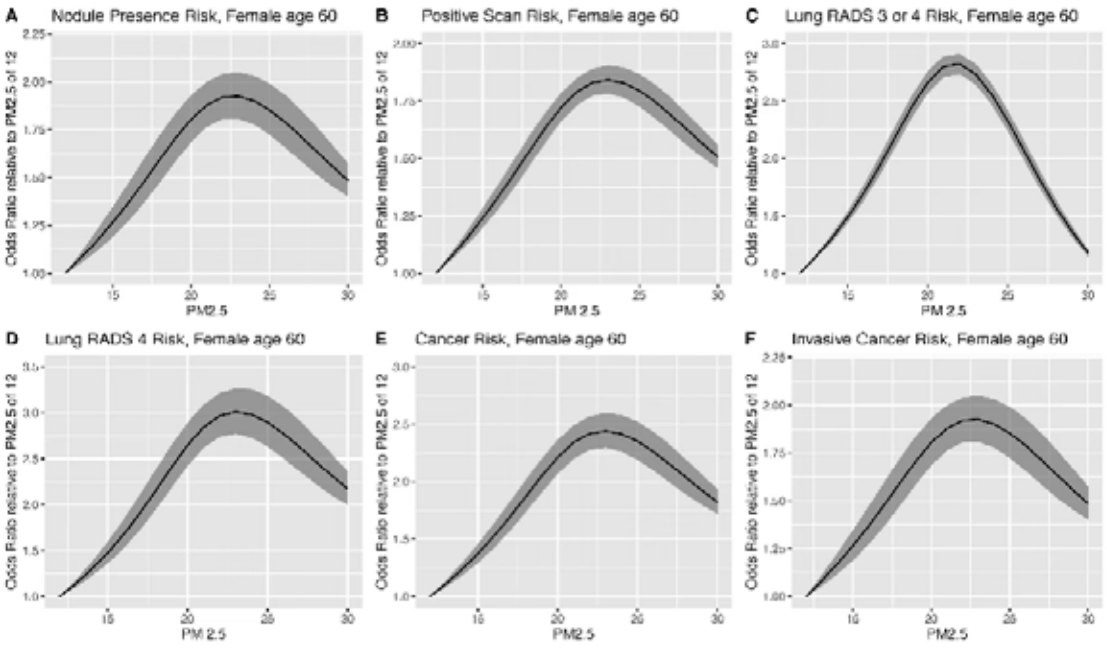

Figure 1. Association between PM2.5 exposure and different lung screening and lung cancer outcomes among never smokers in the TALENT study. A. Presence or not of nodules in the baseline scan. B. Having a positive scan according to the TALENT criteria. C. Having a LungRADS 3 or 4 baseline screening result. D. Having a LungRADS 4 baseline screening result. E. Having a lung cancer diagnosed within a year of the baseline screen. F. Having an advanced lung cancer diagnosed within a year of the baseline screen. PM2.5 exposure was measured based on the average past 3-year annual levels at the baseline residential address. Figures show relative odds for a female aged 60, with no COPD, TB nor first degree relatives with lung cancer.

MA09.02 Impact of Air Pollution and EGFR Mutation on Epigenetic Age and Lung Cancer: A Pilot Study

A.L. McGuire[1], A. Hernandez[2], G. Vaseghi[1], E.L. Lim[3], S. Lam[4], R. Myers[4], J.M. Leung[2]
[1]Vancouver Coastal Health, Vancouver General Hospital, Vancouver/BC/CA ,[2]University of British Columbia and St. Paul's Hospital, Vancouver/BC/CA ,[3]University of British Columbia,, Vancouver/BC/CA ,[4]BC Cancer Research Institute, Vancouver/BC/CA

Introduction: The Global Burden of Disease Study shows that exposure to air pollution is the second leading cause of non-small cell lung cancer (NSCLC). Specifically, fine particulate matter known as PM 2.5 is a major cause of lung cancer in individual with no history of tobacco use. PM 2.5 can induce oxidative stress, affect genetic alterations, and activate oncogenes such as the epidermal growth factor receptor (EGFR), all of which may contribute to the advancement of lung cancer. This study aims to investigate the relationship between PM 2.5 exposure and EGFR mutation status on epigenetic age and the development of lung cancer by investigating the epigenome and epigenetic markers of aging (i.e., epigenetic clocks).

Methods: Lung tissue samples were processed for DNA methylation profiling using the Infinium Methylation EPICv2.0 chip after DNA extraction and bisulfite conversion. Six epigenetic clocks (DNAmAge, DNAmAgeHannum, DNAmAgeSkinBlood, DNAmPhenoAge, DNAmGrimAge1, DNAmGrimAge2, and DNAmTL) were generated from the DNA methylation profiles using the clock foundation web tool (https://dnamage.clockfoundation.org/). We tested the effect of PM 2.5 (20 years exposure) and EGFR mutation on epigenetic age; significant results were defined at $p<0.05$. As measures of global methylation (i.e.; proxy for aging), Alu and Line1 (transposable elements) methylation sites were imputed using the repetitive element methylation prediction machine learning tool. An epigenome-wide methylation analysis was also performed using a robust linear model. Significant differential methylation positions (DMPs) in the epigenome were defined at FDR <0.10. Pathways enrichment analysis was conducted (FDR<0.10)

Results: Sixty-one individuals had available cancerous lung tissue samples with DNA methylation profiling. Of these 39 were female, the cohort's mean age was 67.7 years, 29 were individuals with no history of tobacco use and 15 had an EGFR mutation. The mean PM 2.5 exposure was 7.72 ug/m^3. PM 2.5exposure and EGFR status were not associated with epigenetic age acceleration in any clock. However, in individuals without an EGFR mutation, there was a trend towards significance with higher DNAmSkinBlood age increasing with higher PM 2.5 levels ($p=0.059$). Alu and Line1 methylation showed no significant hypomethylation with either EGFR or PM levels. EGFR mutation was associated with 468 DMPs and 197 (differentially methylated genes) DMGs, while PM 2.5 was associated with 223938 DMPs and 22763 DMGs. Significant pathways associated with PM 2.5 exposure were associated with cancer and aging (e.g., EGFR tyrosine kinase inhibitor resistance and mTOR signaling pathway).

Conclusions: Our findings suggest that while PM 2.5 exposure and EGFR mutation were not directly linked to age acceleration in the lung, they may still have significant epigenetic impacts on biological processes and diseases like cancer and aging. Additionally, a weaker signal was observed in individuals without the EGFR mutation suggesting that higher levels of PM 2.5 exposure may yet be associated with increased epigenetic aging. However, further research within a cohort with greater range of PM 2.5 exposure is necessary to validate these findings and deepen our understanding of the long-term effects of PM 2.5 and EGFR on epigenetic aging and lung cancer.

MA09.03 Determining the Role of Fine Particulate Matter (PM2.5) in Lung Cancer Initiation

P. Wang, J. Naso, R. Myers, C.H. Durney, C. Bartolomeu, A. McGuire, C. MacAulay, S. Lam, W.L. Lam, W.W. Lockwood
University of British Columbia, Vancouver/BC/CA

Introduction: The incidence of lung cancer occurring in people who have never smoked has been continuously rising. Outdoor air pollution, specifically PM2.5- fine particulate matter smaller than 2.5 µm in diameter- has been associated with lung cancer development in this subset of patients, yet the biological role of PM2.5 in lung cancer initiation is largely undefined. This project aimed to investigate the potential of PM2.5 to initiate malignant transformation in vitro.

Methods: Non-transformed lung epithelial cell lines (BEAS-2B and HPL1D) were exposed to PM2.5 in culture. Each PM2.5 exposure involved a 24-hour pulse period followed by recovery before a subsequent exposure was repeated for up to six weeks. A prolonged recovery period up to another six weeks was followed to allow possible mutational burden to accrue. Throughout the exposure timeline, cells were evaluated for various hallmarks of malignant transformation, which included changes in cell morphology, presence of DNA damage and stem-like features, and increase in DNA damage and anchorage independent growth. These cells were also clonally selected and sent for whole exome sequencing to understand the mutational landscape caused by PM2.5 in addition to 55 lung adenocarcinoma patients with defined levels of PM2.5 exposure.

Results: Acute PM2.5 exposures demonstrated significant DNA damage and changes in cell morphology in vitro. Long-term exposures of PM2.5 revealed a relative increase in proliferation and mutational burden as well as a significant increase in colony formation ability in soft agar assays, indicating increased anchorage independent growth. Analysis of the genome of these long-term exposure cells may demonstrate novel somatic variants or pathways altered by PM2.5 exposure.

Conclusions: Taken together, we demonstrate that PM2.5 can drive malignant transformation in normal lung epithelial cells in vitro. This work provides new insights into the role of PM2.5 in lung carcinogenesis, which has the potential to guide lung cancer screening and early detection strategies, particularly in patients who have never smoked.

MA09.04 Maternal Preconception Vaping of Nicotine Induces Severe Airway Remodeling in Offspring and Reduces Airway Progenitor Cells in D. Melanogaster

L. Shi[1,2,3,4], B. Ehrhardt[1], S. Uzenabor[1], T. Roeder[2], S. Krauss-Etschmann[1,5]
[1]Research Center Borstel, Leibniz Lung Center, Borstel/DE ,[2]Christian-Albrechts Universität zu Kiel, Kiel/DE ,[3]Linyi People's Hospital, Linyi/CN ,[4]German Center for Lung Research (DZL), Borstel/DE ,[5]Christian-Albrechts University, Kiel/DE

Introduction: Adolescent vaping raises concerns about intergenerational respiratory health risks. Using Drosophila melanogaster, we explored how maternal preconception nicotine exposure impacts offspring airway architecture and progenitor cell function, focusing on molecular pathways linked to airway remodeling.

Methods: Virgin female flies were exposed to vaporized nicotine (e-nicotine) or control (water). F1 larval tracheae were assessed for structural defects, epithelial remodeling, and stem cell niches. mRNA sequencing of larval tracheae identified dysregulated genes.

Results: Maternal e-nicotine exposure induced severe airway malformations in F1 offspring, including shortened tracheal segments (Tr9: $p<0.001$), increased tracheal deformity rate and epithelia thickness ($p<0.0001$). Stem cell niches (tracheoblast areas) in T4/T5 segments were reduced by 35% ($p<0.0001$), with reduced PH3+ proliferating cells. mRNA sequencing revealed upregulation of genes associated with mucus production (Muc96D, Muc26B), mechanosensation (pie), Notch signaling (E(spl)mbeta-HLH), and RNA processing (Rpp30, NHP2). Additional dysregulated genes included Syb (synaptic function), hzg (cell adhesion), MAN1 (chromatin regulation), and Npc2a (lipid metabolism), suggesting broad disruption of developmental and homeostatic pathways.

Conclusions: Preconception nicotine exposure in Drosophila models triggers airway remodeling, stem cell depletion, and dysregulation of genes critical for epithelial integrity and signaling. Future studies will focus on ongoing mRNA sequencing of T4/T5 tracheoblast niches to uncover deeper molecular mechanisms linking maternal e-nicotine exposure to intergenerational airway dysfunction. These findings underscore potential intergenerational harms of adolescent vaping, warranting further investigation into nicotine's impacts on respiratory health.

MA09.05 The Effect of Lung Cancer Screening on Smoking Behaviors - No Evidence of a 'License to Smoke' Effect

M. Callister[1], F. Pesola[2], R. Gabe[2], H. Beal[1], P.A. Crosbie[3], N. Hancock[4], J. Lindop[1], C. Marshall[4], S. Rogerson[1], R. Thorley[5], R. Murray[5]
[1]Leeds Teaching Hospitals NHS Trust, Leeds/GB ,[2]Queen Mary University London, London/GB ,[3]The University of Manchester, Manchester/GB ,[4]University of Leeds, Leeds/GB ,[5]University of Nottingham, Nottingham/GB

Introduction: The effect of lung cancer screening (LCS) on smoking behaviour is unclear with previous randomised studies demonstrating either increased quit rates in people screened versus unscreened controls (suggesting a teachable moment for smoking cessation at screening) or reduced quit rates in people screened (possibly suggesting a license-to-smoke effect of screening). Here we report the impact of LCS on smoking cessation service use and quit rates in the intervention vs. controls arms of the Yorkshire Lung Screening Trial (YLST).

Methods: In YLST, people aged 55-80 who had ever smoked were randomised to invitation to lung cancer risk assessment and if high-risk then LDCT screening, or control arm (no invitation to screening). LCS was not approved in the UK at the time of participant randomisation. Smoking cessation service interaction, defined as undertaking a consultation with a smoking cessation practitioner (SCP), and self-reported smoking quits were recorded during the study period. Smoking cessation services included (1) the YLST-service which was co-located with screening and available to screening attendees and (2) a local authority (LA) provided service available to all residents of Leeds (and thus available to both study arms). Differences in reporting metrics between the two services preclude direct statistical comparison of quit rates at this time although ongoing analysis is underway attempting to harmonise data and will be presented in due course.

Results: Data is presented on 43,852 people in the control arm and 43,942 people in the intervention arm (of whom 24,587 [56.0%] responded and underwent lung cancer risk assessment and 7,384 [16.8%] underwent LDCT screening). Primary care diagnostic codes suggested that 12,241 and 12,182 people in the intervention and control arms respectively were actively smoking at the time of randomisation. Overall, 5.8% (n=2,542/43,942) of the intervention arm saw an SCP compared to 1.5% (n=675/43,852) of the control arm (OR 3.92, 95%CI 3.60-4.28, p<0.0001). Self-reported quit rates are shown in Table 1. Differences in reporting metrics preclude statistical comparison but overall a higher proportion of people appear to self-report quitting in the intervention versus control arm.

	Control arm	Intervention arm
Total number of participants (irrespective of smoking code)	43,852	43,942
Number meeting with an SCP (%)	675 (1.5)	2,542 (5.8)
14-day point prevalent quits at 4 weeks with LA service (%)	264 (0.6)	198 (0.5)
7-day point prevalent quits at 4 weeks with YLST service (%)	-	471 (1.1)
7-day point prevalent quits at 12 weeks with YLST service (%)	-	613 (1.4)
Total number of participants with Primary Care smoking code suggesting active smoking at time of randomisation	12,241	12,182
Number meeting with an SCP (%)	567 (4.6)	2,212 (18.2)
14-day point prevalent quits at 4 weeks with LA service (%)	206 (1.7)	146 (1.2)
7-day point prevalent quits at 4 weeks with YLST service (%)	-	383 (3.1)
7-day point prevalent quits at 12 weeks with YLST service (%)	-	520 (4.3)

Table 1: Number of participants meeting an SCP and self-reported quits with LA and YLST services.

Conclusions: YLST is the first study to compare smoking behaviours between a whole population invited for LCS and a non-invited control population. Compared to the control population, over three times as many people in the intervention arm saw an SCP and more quits were reported. These data provide reassurance that LCS provides a teachable moment for smoking cessation with no dominant licence-to-smoke effect.

Keywords: Low dose CT screening, Smoking cessation

MA09.06 Impact of Smoking Cessation at Diagnosis on Overall Survival in Lung Cancer Patients: A Comprehensive Meta-Analysis

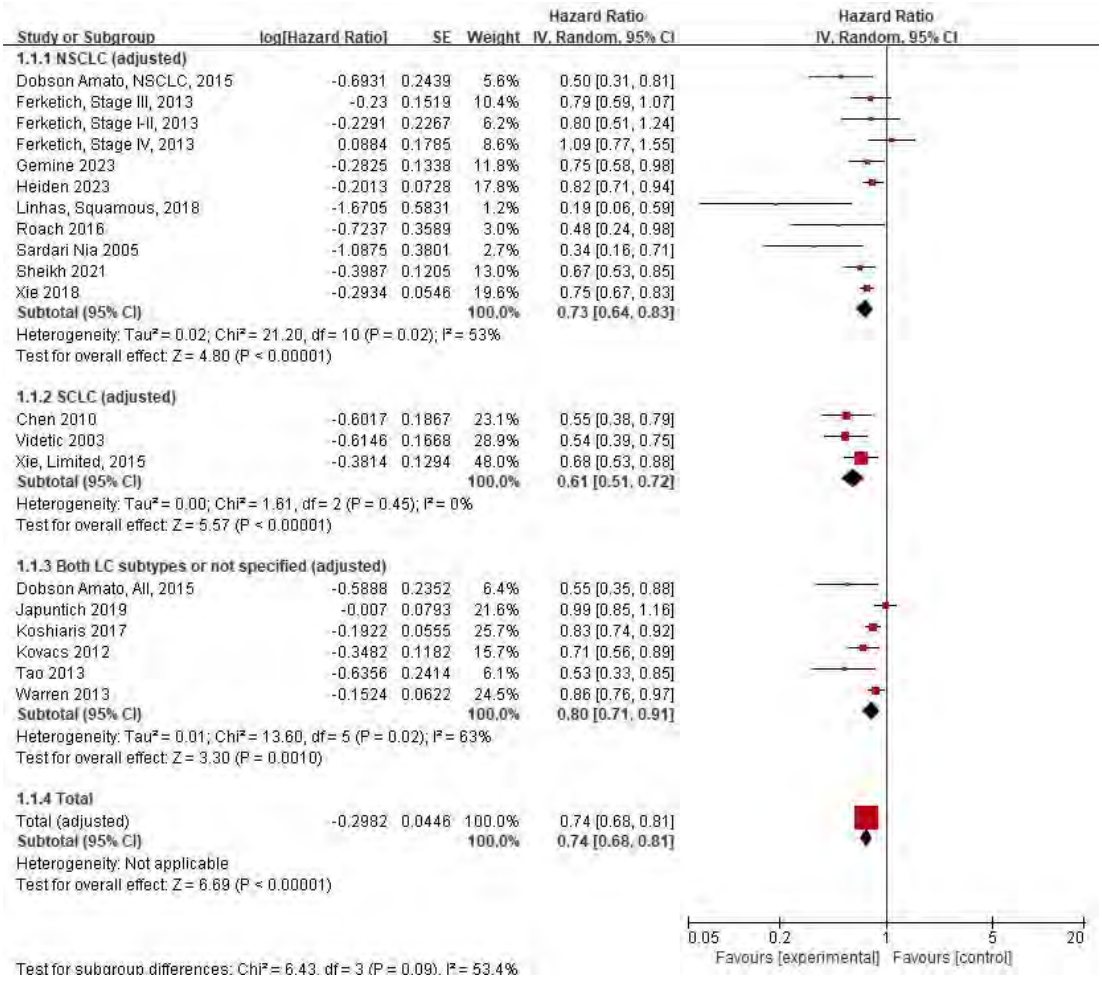
J.M. Lee[1], H-W. Suh[2], H-J. Lee[2], M. Choi[2], J.S. Kim[3,4], K. Lee[3,4], H. Lee[5], S-H. Kim[5], J.W. Sohn[5], H.J. Yoon[5], Y-J. Paek[6], C.M. Lee[7], D.W. Park[5]
[1]Seoul St. Mary's Hospital College of Medicine, Catholic University of Korea, Seoul/KR ,[2]National Evidence-based Healthcare Collaborating Agency, Seoul/KR ,[3]Seoul National University College of Medicine, Seoul/KR ,[4]Seoul National University Bundang Hospital, Seongnam/KR ,[5]Hanyang University College of Medicine, Seoul/KR ,[6]Hallym University Sacred Heart Hospital, Anyang/KR ,[7]Seoul National University Hospital Healthcare System Gangnam Center, Seoul/KR

Introduction: Smoking cessation has been linked to reduced lung cancer mortality in the literature. This study aims to synthesize scientific evidence on the impact of smoking cessation at or around the time of diagnosis on survival outcomes in lung cancer patients, with a specific focus on whether the effect varies by lung cancer stage.

Methods: A systematic search was conducted in Ovid-MEDLINE, Ovid-EMBASE, Cochrane Central Register of Controlled Trials, and KoreaMed databases up to September 2024. Randomized controlled trials and cohort studies comparing smoking quitters with continued smokers at diagnosis were included. The primary outcome was overall survival (minimum follow-up of three months). The included studies were critically appraised using the Cochrane risk of bias tool and meta-analyzed.

Results: A total of 25 cohort studies including 17,584 patients were included. We found that smoking cessation at diagnosis was associated with a significant reduction in mortality risk, with an adjusted HR of 0.74 (95% CI: 0.68-0.81) for all lung cancer patients. Furthermore, in subgroup analyses, smoking cessation was associated with improved survival in both non-small cell lung cancer (adjusted HR: 0.73, 95% CI: 0.64-0.83) and small cell lung cancer (adjusted HR: 0.61, 95% CI: 0.51-0.72). Subgroup analyses showed a more pronounced benefit of smoking cessation in patients with early-stage disease (Stage I-III or limited stage, adjusted HR: 0.64, 95% CI: 0.56-0.74). In addition, active smoking cessation interventions significantly improved survival (adjusted HR: 0.55, 95% CI: 0.35-0.88). However, this impact of smoking cessation on survival needs to be further investigated as few studies objectively confirmed smoking cessation.

Conclusions: This study highlights the importance of encouraging smoking cessation at the time of lung cancer diagnosis as an integral part of patient management to improve survival outcomes. Future research should focus on identifying effective smoking cessation strategies to maximize survival benefits for lung cancer patients.



Keywords: Lung cancer, smoking cessation, survival

MA09.07 Body Roundness Index and Polygenic Risk Score Improve Lung Cancer Risk Prediction Over BMI: Prospective Analyses in the UK Biobank

W. Li, Z. Lyu, M. Xing, Y. Cong, K. Chen
Tianjin Medical University and Hospital, Tianjin/CN

Introduction: Obesity is a well-established risk factor for multiple cancers, including lung cancer. However, traditional metrics like Body Mass Index (BMI) fail to capture body fat distribution, a critical determinant of metabolic dysregulation. The Body Roundness Index (BRI), a novel anthropometric measure derived from waist circumference and height, better reflects visceral adiposity and associated health risks. Concurrently, the polygenic risk score (PRS) quantifies genetic susceptibility to cancer. This study aims to investigate the joint associations of BRI and PRS with lung cancer incidence and mortality and compare their predictive performance against BMI in a large prospective cohort.

Methods: We utilized data from the UK Biobank to investigate the associations between the BRI and both lung cancer incidence and cancer mortality. BRI was calculated according to the following formula: BRI = $364.2 - 365.5 \times \sqrt{(1 - (\text{waist circumference} / (2\pi))^2 / (\text{height} / 2)^2)}$. PRS for lung cancer were derived using genome-wide significant SNPs ($p < 5 \times 10^{-8}$), weighted by effect sizes from prior GWAS. Participants were categorized into three groups based on BRI and PRS quintiles. Cox proportional hazards models were used to evaluate the relationships between BRI and these outcomes. To evaluate the predictive capabilities of BRI and BMI for cancer outcomes, receiver operating characteristic (ROC) analysis and area under the curve (AUC) metrics were employed. The DeLong test was used to statistically compare the AUCs of BRI and BMI.

Results: This study included 442,525 participants, among whom 4,083 lung cancer cases and 2,902 lung cancer-related deaths were identified. After adjusting for age, sex, ethnicity, education level, smoking status, alcohol consumption, and family history of cancer, individuals in third quintile (Q3: 4.58 to 23.55) had a 1.16-fold (95% CI: 1.07 - 1.26) increased risk of lung cancer incidence and a 1.13-fold (95% CI: 1.03 - 1.25) higher risk of lung cancer mortality compared to those in the lowest quintile (Q1: -1.08 to 3.36). In the high-risk PRS group, individuals in the third quintile of BRI had a 1.21-fold (95% CI: 1.06-1.37) higher risk of lung cancer incidence and a 1.17-fold (95% CI: 1.01-1.36) increased risk of lung cancer mortality compared to those in the lowest BRI quintile. ROC analysis indicated that the combination of BRI and PRS (AUC incidence= 0.58, AUC mortality= 0.58) outperformed the combination of BMI and PRS (AUC incidence = 0.51, AUC mortality= 0.51) in predicting both lung cancer incidence and mortality ($p < 0.05$).

Conclusions: BRI is a stronger predictor of lung cancer incidence and mortality than BMI, with enhanced discrimination when combined with PRS. These findings support integrating BRI and genetic risk for precision risk stratification, potentially guiding targeted prevention strategies.

MA09.08 Germline Variants in Indian NSCLC Patients With Familial Aggregation: A Prospective Cohort Study

P.S. Malik[1], A. Agrawal[1], S.D. Chitikela[1], R. Pramanik[1], S. Khurana[1], D. Pushpam[1], A. Sharma[1], D. Jain[1], I. Gupta[2]
[1]All India Institute of Medical Sciences, New Delhi, New Delhi/IN ,[2]Indian Institute of Technology, Delhi/IN

Introduction: While tobacco exposure is a primary risk factor for lung cancer, not all individuals with a history of tobacco use develop the disease, and cases in individuals without such exposure are rising, highlighting the role of genetic susceptibility. Pathogenic or likely pathogenic germline variants (PGVs) in cancer predisposition genes are increasingly recognized in various cancers including lung cancer, particularly those who have familial aggregation. This study investigates the prevalence of PGVs in individuals with Indian non-small cell lung cancer (NSCLC) who have a significant family history.

Methods: A total of 750 individuals with NSCLC were screened for familial aggregation, defined as having at least one first-degree or two second-degree relatives with cancer. Of these, 112 individuals underwent next-generation sequencing (NGS) of targeted 143 cancer predisposition genes or whole exome sequencing using blood samples. Clinical, pathological, and demographic data were analyzed. Survival analysis was performed using Kaplan-Meier estimates, and statistical comparisons were conducted with the chi-square and Mann-Whitney U tests.

Results: Among 750 individuals, 137 (18.26%) had a significant family history. NGS in 112 individuals revealed PGVs in 17 participants (15.2%). These PGVs were distributed across 12 genes, with 10 genes linked to DNA damage repair pathways, including ATM (n=3), BRCA2 (n=3), BRCA1 (1) and CKEK2 (1) . Moreover, 12 individuals were identified with variants of uncertain significance (VUS), including MUC5B (n=7), and one each in POLE, PRKN, DLEC1, KRAS, ERBB2, and BRAF. Individuals with PGVs did not exhibit statistically significant differences in clinical characteristics compared to those without.

Conclusions: This study demonstrates that 15.2% of individuals with Indian NSCLC and familial aggregation harbor PGVs, predominantly in DNA repair genes. The findings underscore the need for genetic testing in individuals with lung cancer who have a strong family history, which could aid in risk assessment and personalized screening strategies.

MA09.09 Unraveling Ancestry Disparities and Intratumoral Heterogeneity in Non-Small Cell Lung Cancer

Y. He[1,2], W. Wang[1,2], J. Bai[3,4], J. Xu[5], J. Bai[5], K. Chen[1,2]
[1]Peking university people's hospital, Beijing/CN ,[2]Chinese Academy of Medical Sciences, Beijing/CN ,[3]Peking University, Beijing/CN ,[4]Geneplus-Beijing Institute, Beijing/CN ,[5]Kanghui biotech, Beijing/CN

Introduction: Lung cancer remains the leading cause of cancer-related mortality worldwide, with significant racial disparities observed in its incidence, epidemiological characteristics, molecular profiles and so on. These differences between Eastern and Western populations profoundly influence treatment strategies and patient prognosis. However, the majority of studies characterizing the molecular landscape of lung cancer have predominantly focused on Western cohorts and have often relied on single tumor region sampling, thereby overlooking racial molecular variations and intratumoral heterogeneity (ITH).

Methods: To address these gaps, we performed whole exome sequencing (WES) and RNA sequencing (RNA-seq) on 290 Chinese lung cancer patients with multiregional tumor and matched paired normal samples (called CLEVER cohort, Chinese Lung Cancer EVolution and MicroEnironment tracking under TheRapy). Systematic comparison with published data from the TRACERx cohort, comprising 365 lung tumors, revealed significant differences in the genomic and transcriptomic molecular signatures and the timing of evolutionary trajectories between Eastern and the Western lung cancer patients.

Results: The CLEVER cohort demonstrated significant epidemiological differences, including higher proportions of female patients, non-smokers, younger age at diagnosis, earlier tumor stages, and adenocarcinoma predominance. At the genomic level, CLEVER tumors exhibited elevated subclonal complexity compared to TRACERx, with significantly higher subclonal heterogeneity metrics including higher single nucleotide variation intratumor heterogeneity (SNV-ITH) and higher somatic copy number alteration ITH (SCNA-ITH) and increased subclonal whole-genome duplication (WGD) events. Comparative analysis revealed distinct clonal architectures of driver genes between two cohorts: EGFR, HMCN1, and KMT2B mutations preferentially occurred as truncal events in CLEVER, whereas KRAS mutations were predominantly subclonal. Chromosomal arm-level analysis revealed CLEVER-specific CNV patterns, including increased subclonal amplifications (5p, 8q) and deletions (3p, 9p, 19p), alongside truncal 8p deletions. Transcriptomically, the CLEVER cohort displayed reduced heterogeneity compared to TRACERx. Most transcriptional genes exhibited low intra- and intertumoral heterogeneity and were enriched in ligand-receptor interaction pathways and signal transduction cascades. Collectively, these findings demonstrate that Asian lung cancers are characterized by enhanced genomic intratumor heterogeneity driven by subclonal WGD dynamics and late-acquired drivers, and reduced transcriptional heterogeneity associated with stable signaling circuitries- a dual evolutionary paradigm distinct from Western populations.

Conclusions: These discoveries underscore the importance of population context in deciphering comprehensive molecular maps and tumor evolution for lung cancer.

[1]Sun Yat-Sen University Cancer Center, Guangzhou/CN ,[2]Cancer Center, Meizhou People's Hospital (Huangtang Hospital), Meizhou Academy of Medical Sciences, Meizhou/CN ,[3]Tenth Affiliated Dongguan Hospital, Southern Medical University (Dongguan people's hospital), Dongguan/CN ,[4]The First Affiliated Hospital of Guangxi Medical Universuty, Nanning/CN ,[5]The First People's Hospital of Foshan, Foshan/CN ,[6]Guangdong Provincial Hospital of Chinese Medicine, Guangzhou/CN ,[7]Cancer Hospital of Shantou University Medical College, Shantou/CN

Introduction: The efficacy of immunotherapy for non-small-cell lung cancer (NSCLC) with brain metastases (BMs) remains limited. The tumor immune response property of serplulimab may be simultaneously enhanced by the blockade of vascular endothelial growth factor. This study evaluated the efficacy and safety of serplulimab combined with bevacizumab and chemotherapy as a first-line treatment for patients with NSCLC and untreated BMs.

Methods: This single-arm phase 2 clinical trial (NCT05807893) enrolled patients with advanced non-squamous NSCLC with untreated BMs that were either asymptomatic or had symptoms controlled by dehydration therapy. Patients received serplulimab combined with bevacizumab, pemetrexed, and carboplatin for four to six cycles, followed by maintenance therapy with serplulimab plus bevacizumab and pemetrexed until disease progression, unacceptable toxicity, or death, for up to two years. The primary endpoint was intracranial progression-free survival (iPFS). Intracranial outcomes were assessed using the modified Response Evaluation Criteria in Solid Tumors (mRECIST) version 1.1.

Results: Forty patients were enrolled, and 39 had at least one postbaseline tumor assessment. As of 17 February 2025, the median follow-up duration was 13.3 months (95% confidence interval [CI]: 13.0-13.5). The median iPFS was 13.1 months (95% CI 12.7-not reached), with 6-month and 12-month iPFS rates of 91.3% (95% CI 82.3%-100.0%) and 67.1% (95% CI 51.1%-88.1%) respectively. The median PFS was 13.3 months (95% CI 11.9-not reached). Nine patients (22.5%) died due to disease progression, and the 12-month overall survival (OS) rate was 73.1% (95% CI 63.7%-92.6%). The intracranial ORR was 84.6% (33/39), with complete response (CR) in 6 patients (15.4%) and partial response (PR) in 27 patients (69.2%). The extracranial ORR was 67.7% (25/39), and the overall ORR was 71.8% (28/39). The most common treatment-related adverse events (TRAEs) of grade 3 or higher included decreased white blood cell/neutrophil count (4 patients [10.0%]), reduced platelet count (5 patients [12.5%]), and abnormal liver function (4 patients [10.0%]). No treatment-related deaths were reported.

Conclusions: Serplulimab plus bevacizumab and chemotherapy demonstrated promising intracerebral antitumor efficacy and a manageable safety profile for patients with non-squamous NSCLC with BMs in the first-line setting.

Introduction: PD-(L)1 inhibitors combined with chemotherapy have become the first-line standard-of-care (SOC) for advanced non-small cell lung cancer (NSCLC). This prospective, multi-center, phase 1b/2 study (NCT05142423) aims to evaluate the safety and efficacy of cadonilimab, a PD-1/CTLA-4 bispecific antibody, in combination with pulocimab, an anti-VEGFR-2 monoclonal antibody, in patients with advanced solid tumors, including those with NSCLC who have progressed after first-line SOC immunotherapy-based treatment.

Methods: This study consists of two phases: a safety run-in phase and an expansion phase. In the safety run-in phase, the safety of intravenous cadonilimab (10 mg/kg) in combination with pulocimab (10 mg/kg and 15 mg/kg),with or without chemotherapy, every 3 weeks (Q3W), were assessed in patients with advanced solid tumors who had failed standard treatments. This abstract focuses on the NSCLC cohort from the expansion phase. Patients with advanced NSCLC who had progressed after first-line immunotherapy-based SOC treatment received intravenous pulocimab (15 mg/kg) and cadonilimab (10 mg/kg), Q3W. The primary endpoints were safety and objective response rate (ORR), while secondary endpoints included disease control rate (DCR), duration of response (DOR), progression-free survival (PFS), and overall survival (OS).

Results: No dose-limiting toxicities (DLTs) were observed in the safety run-in phase (n=18). As of January13, 2025, a total of 47 NSCLC patients who had progressed on first-line immunotherapy-based SOC treatment received at least one dose of cadonilimab and pulocimab, with a median follow-up of 16.7 months (range: 8.1-19.0). All 47 patients had at least one post-baseline tumor evaluation. The ORR was 12.8% (6/47), DCR was 95.7% (45/47), median DOR was 15.2 months, median PFS was 5.8 months, and median OS was 15.6 months. Among them, 26 patients had squamous NSCLC, with an ORR of 11.5% (3/26), DCR of 96.2% (25/26), median DOR not reached, median PFS of 7.1 months, and median OS of 16.7 months, indicating a more pronounced therapeutic effect in the squamous subgroup. For the 21 non-squamous NSCLC patients, the ORR was 14.3% (3/21), DCR was 95.2% (20/21), median DOR was 8.8 months, median PFS was 5.5 months, and median OS was 12.8 months. The incidence of grade ≥3 treatment-emergent adverse events (TEAEs) was 36.2%, while the incidence of grade ≥3 treatment-related adverse events (TRAEs) was 21.3%. The most common TRAEs included elevated aspartate aminotransferase, thrombocytopenia, and proteinuria. The only Grade ≥3 TRAEs that occurred in more than two patients was hypertension. No new safety signals were identified.

Conclusions: The combination of cadonilimab and pulocimab demonstrated favorable safety profile and encouraging efficacy as second-line therapy in patients with NSCLC who progressed after prior first-line immunotherapy-based SOC treatment, with particularly notable efficacy in the squamous NSCLC subgroup. These findings suggest that this combination may overcome immunotherapy resistance and offer a potential new option for second-line treatment of NSCLC. A further phase III clinical trial is currently in planning.

Introduction: In recent years, the first-line immunotherapy has become an essential tool in the personalized treatment of NSCLC patients. Despite a proper diagnostic procedure for qualification for the therapy, many patients do not respond to the therapy regardless of PD-L1 expression on tumor cells. This may be caused by differences in tumor heterogeneity and temporal clonal evolution. To reveal mechanisms of immunotherapy failure, we performed low-pass whole genome sequencing (lp-WGS) to investigate the dynamics of subclonal copy number alterations (CNAs) changes across primary tumors (T) and longitudinal liquid biopsies (LB).

Methods: We collected T and LB1 samples before the treatment application and further longitudinal LB samples (LB2, LB3, etc) approximately every 2-3 months during clinical follow-up until therapy completion. The lp-WGS was performed on NextSeq 550 instrument (Illumina, USA). The R package inchorCNA was used to call and asses the subclonal evolution of CNAs and GISTIC2.0 to localize the significant focal somatic CNAs. The P value of < 0.05 (Wilcoxon paired test) was considered statistically significant. This study was funded by the Polish National Centre for Research and Development (LIDER/46/0237/L-12/20/NCBR/2021).

Results: We shallowly sequenced 520 samples (93-T, 128-LB1, 89-LB2, 55-LB3, 41-LB4, 33-LB5, 25-LB6, 21-LB7, 15-LB8, 9-LB9, 9-LB10, 5-LB11) from 128 patients (73 males, 55 females; median age 67±8 years) treated with pembrolizumab in monotherapy (48) or in combination with chemotherapy (80) (median PFS: 3 months). Among them, 35 patients were long responders (PFS >12 months), while 93 were short responders (PFS ≤12 months), including 55 treated for ≤3 months, 19 for 3-6 months, and 19 for 6-12 months. Subclonal analysis revealed significant differences between T and LB1, suggesting early pre-treatment clonal selection. Long responders exhibited a gradual reduction in subclonal diversity (LB3/LB4, LB5/LB6), whereas short responders experienced rapid subclonal shifts within the first observation period (LB1/LB2, LB3/LB4), indicating early selection of resistant clones. Amplification of 3q26 was detected in T and LB1 samples across all patients, regardless of response duration. Long responders harbored also a 4q34 deletion and 12q14 amplification, while short responders exhibited a more heterogeneous CNAs profile, which included amplifications of 3q24-28, 8p11, and 19q12, or deletions of 8p23 and 9p21. LB samples obtained in long responders at the moment of progression showed persistent 3q26 amplification and newly acquired focal amplifications of 8q22 and 6q16, or 21q21 deletion.

Conclusions: Our study demonstrates that lp-WGS of longitudinal liquid biopsies reveals distinct evolutionary trajectories of clonal evolution associated with pembrolizumab response in NSCLC patients. In short responders, resistant subclones may already be present before therapy initiation, leading to rapid subclonal shifts within early treatment cycles. In contrast, long responders exhibited a gradual reduction in subclonal diversity, suggesting effective suppression of tumor heterogeneity, followed by the emergence of new CNAs potentially driving secondary resistance. The presence of 3q26 amplification across all patients suggests its role as a key driver of immunotherapy resistance in NSCLC patients.

TUESDAY, SEPTEMBER 9, 2025 - 13:00 - 14:15

MA10.05 Phase I/II Study of Nivolumab and Ipilimumab With Concurrent Stereotactic Radiosurgery for Intracranial Metastases From NSCLC

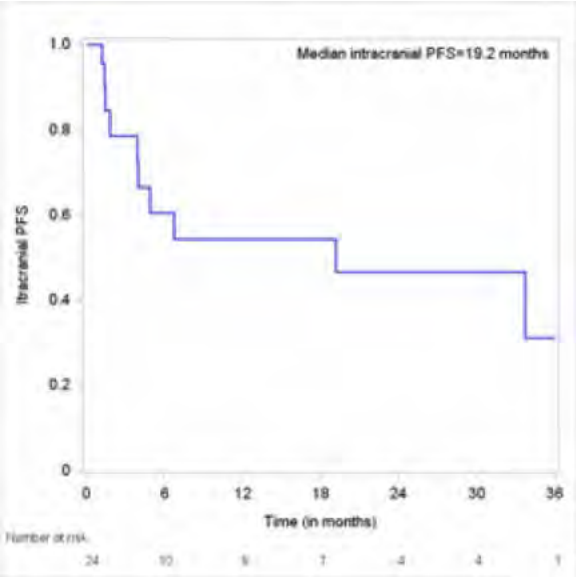
M. Altan, T. Beckham, J. Song, J. Welsh, N. Guha-Thakurta, B. Carter, G. Blumenschein, Y. Elamin, C. Tang, A. Ghia, D. Yeboa, M.F. McAleer, C. Chung, S.L. McGovern, C. Wang, T. Martin, S. Perni, W. Jiang, B.S. De, J.S. Wefel, Y. Wang, J. Hicks, Y.S.B. Kim, J. Weinberg, T.M. Briere, X. Le, T. Cascone, M. Vailati Negrao, F. Skoulidis, R. Ferrarotto, J.V. Heymach, J. Li
MD Anderson Cancer Center, Houston/TX/USA

Introduction: As many as 20% of patients with non-small cell lung cancer (NSCLC) experience brain metastases (BM), for which radiation therapy, with or without surgery, remains the standard treatment. However, clinical data on the safety of combining stereotactic radiosurgery (SRS) with immune checkpoint inhibitors for BM are lacking.

Methods: We conducted a single institution, open label, phase I/II study, enrolled NSCLC patients with active brain metastases (BM) eligible for stereotactic radiosurgery (SRS). Patients received brain SRS alongside systemic therapy with nivolumab and ipilimumab within a 7-day window. The primary endpoints were safety and intracranial progression-free survival (PFS) at four months.

Results: Twenty-four patients were enrolled in the study, with a median follow-up of 41.6 months (95% CI, 36.7-53.3). The median overall survival was 20.2 months, while the median time to intracranial progression or death was 19.2 months (95% CI, 3.9-36.2). The median time to extracranial progression or death was 19.2 months (95% CI, 1.4- 36.2). No treatment failures were observed within the radiation field for brain metastases during follow up period, leading to a local control rate of 100% from SRS. The 4-, 6-, and 12-month intracranial progression-free survival (PFS) rates were 66.4%, 60.4%, and 54.3%, respectively. Only one patient experienced a predefined dose-limiting toxicity, developing cerebral edema attributed to concurrent SRS and immunotherapy, which was successfully managed and resolved with steroids.

Conclusions: In this study, concurrent brain SRS with nivolumab/ipilimumab was safe for patients with active NSCLC BM, with acceptable toxicity profile. Intracranial PFS rates (70% vs. historical ~50% at 6 months) and the median time to intracranial progression or death (19.2 months vs. historical ~ 5-10 months) compare favorably to historical data with SRS alone, highlighting the potential impact of this approach.



Keywords: brain metastasis, immunotherapy, stereotactic radiosurgery

MA10.06 IMscin002 Final Analysis: Patient Preference and Safety of Atezolizumab by Subcutaneous and Intravenous Administration

F. Cappuzzo[1], Z. Zvirbule[2], E. Korbenfeld[3], J. Kolb-Sielecki[4], D. Isla[5], A.Y. Castro Sanchez[6], A. Bustillos[6], L. Herraez-Baranda[6], T. Barata[6], F. Young[7], M. Majem[8]

Hoffmann-La Roche AG, Basel/CH ,[7]F. Hoffmann-La Roche Ltd, Welwyn Garden City/GB ,[8]Hospital de la Santa Creu i Sant Pau, Barcelona/ES

Introduction: Atezolizumab subcutaneous (SC), a co-formulation containing atezolizumab and recombinant human hyaluronidase PH20, is approved for the same indications as atezolizumab intravenous (IV). IMscin001 (NCT03735121) showed the pharmacokinetics, efficacy, and safety of atezolizumab SC and IV were consistent. IMscin002 (NCT05171777), a phase II, randomized, open-label, cross-over trial, investigated patient preferences, healthcare professional (HCP) perceptions, and safety for atezolizumab SC versus IV in patients with non-small cell lung cancer (NSCLC); we report results from the final analysis.

Methods: Eligible adults with EGFR/ALK wildtype had PD-L1+ resected (stage II, IIIA/B; AJCC 8th edition) NSCLC and completed adjuvant chemotherapy without evidence of recurrence, or were treatment-naïve with PD-L1-high metastatic NSCLC. Patients, randomized 1:1, received atezolizumab SC (1875mg) or IV (1200mg) every 3 weeks. After Cycle 3, patients switched formulations, and after Cycle 6 patients chose an administration route for the continuation period (10 additional cycles for early-stage, or until investigator-determined loss of clinical benefit for patients with resected/metastatic NSCLC). Primary endpoint: patient preference for atezolizumab SC. Secondary endpoints included choice of administration route for the continuation period, safety, and patient-reported outcomes (PROs; captured via the EORTC QLQ-C30).

Results: At data cutoff (last patient's last visit; October 25, 2024), 179 patients were randomized; 90 to atezolizumab SC followed by IV, and 89 to atezolizumab IV followed by SC. Overall, 115 (64.2%) and 43 (24.0%) patients completed the cross-over and continuation periods, respectively. Most patients (77.4%; n=89/115) chose atezolizumab SC for the continuation period, with 22.6% (n=26/115) opting for atezolizumab IV. Median treatment duration was 10.4 months; median number of cycles initiated was 14 (range: 1-36). The safety profile of atezolizumab SC/IV was consistent with the primary analysis and established safety profile of atezolizumab; 80.6% (n=141/175) of patients experienced ≥1 adverse event (AE; 54.9% treatment-related). Nineteen (10.9%) and 4 (2.3%) patients experienced injection-site reactions and infusion-related reactions, respectively (Table). At or after 16 cycles, 44.7% (n=80/179) of patients had ongoing clinical benefit; 61.3% (n=38/62) with early-stage NSCLC and 35.9% (n=42/117) with metastatic NSCLC. During the continuation period, mean changes from baseline in PROs (global health status [GHS], physical and role functioning) aligned with the primary analysis. GHS, physical and role functioning, and symptom scales showed similar results.

Conclusions: No new or unexpected safety findings were observed. Longer term data support that most patients prefer atezolizumab SC versus IV, and that atezolizumab SC has similar efficacy, PROs, and a similar safety profile to atezolizumab IV.

Table

Patients, n (%)	Cross-over period		Continuation period		All patients (N=175)‡
	Atezolizumab IV* (n=160)	Atezolizumab SC† (n=155)	Atezolizumab IV (n=26)	Atezolizumab SC (n=89)	
≥1 AE	95 (59.4)	74 (47.7)	20 (76.9)	60 (67.4)	141 (80.6)
Injection-site reactions	0	16 (10.3)	0	3 (3.4)	19 (10.9)

Introduction: Nivolumab (NIVO) plus relatlimab (RELA) with platinum-doublet chemotherapy (PDCT) is being investigated in a phase 3 study as a first-line treatment for patients with metastatic NSCLC having tumor PD-L1 expression ≥1% and non-squamous histology. Patients receiving PDCT-containing regimens often require prophylactic myeloid growth factors (MGFs; eg, G-CSF) to prevent neutropenia. However, the impact of MGFs on immunotherapy + PDCT (eg, NIVO + RELA + PDCT) outcomes is not well explored. We investigated how MGF support influences outcomes in patients receiving NIVO + RELA + PDCT in the phase 2 RELATIVITY-104 trial and performed complementary in vitro experiments to explore the immunologic effects of MGFs.

Methods: Patients in RELATIVITY-104 had untreated metastatic NSCLC. Part 1 evaluated the safety of NIVO 360mg + RELA (360mg or 720mg) + PDCT Q3W. In Part 2, patients received NIVO 360mg + RELA 360mg + PDCT or NIVO 360mg + PDCT Q3W. Based on the safety profile and observations during Part 1, prophylactic MGF was mandated in the NIVO + RELA + PDCT arm in Part 2 for patients aged ≥60 years and used therapeutically for patients aged <60 years experiencing grade ≥3 neutropenia. Prophylactic MGF was allowed but not mandatory in the NIVO + PDCT arm in Part 2 and the NIVO + RELA + PDCT arms in Part 1. Exploratory analyses included clinical outcomes by MGF use, assessment of pharmacodynamic changes of myeloid cells by flow cytometry in the context of MGF use, and the phenotypic and functional impact of MGF-treated myeloid cells on immunobiology in vitro.

Results: Data are from the Feb 15, 2024 (Part 1) and June 28, 2024 (Part 2) database locks. In the NIVO + RELA + PDCT arm of Part 1 (no prophylactic MGFs), 66% of patients experienced grade 3-4 treatment-related adverse events (TRAEs). In Part 2 (prophylactic MGFs), 54% of patients treated with NIVO + RELA + PDCT and 55% of patients treated with NIVO + PDCT experienced grade 3-4 TRAEs. Grade ≥3 treatment-related neutropenic events were observed in 42% (Part 1) and 26% (NIVO + RELA + PDCT arm in Part 2) of patients; objective response rates were 45% (Part 1) and 51% (Part 2) in all randomized patients. In vitro analyses suggested no substantial impact on the phenotype of MGF-treated myeloid-derived suppressor cells (MDSCs) and MGF-treated monocytes compared with untreated cells. MGFs did not increase MDSC suppressive activity against CD8+ T cell proliferation or IFN-γ production. Clinically, MDSC/lymphocyte or monocyte/lymphocyte ratios remained similar following prophylactic MGF use in the NIVO + RELA + PDCT arm relative to patients not treated with MGF and the NIVO + PDCT arm.

Conclusions: In patients with metastatic NSCLC treated with first-line NIVO + RELA + PDCT, prophylactic MGF did not compromise efficacy and meaningfully reduced hematologic toxicity. Taken together, these results support prophylactic MGF use with dual immunotherapy + PDCT regimens in patients with NSCLC. Use of MGFs did not appreciably modulate myeloid cell phenotype, increase their prevalence, or alter their functional effects on T cells.

MA10.08 Anti-PD-1 Re-Challenge After Immune Priming by CTLA-4 Inhibition and Immune Boosting Through Radiotherapy in Advanced NSCLC: The RAD-IO Trial

D. van der Geest
NKI-AvL, Amsterdam/NL

Introduction: In advanced non-small cell lung cancer (NSCLC) without targetable driver alterations, current first line standard-of-care treatment consists of PD-(L)1 inhibition with or without chemotherapy. The majority of patients does not experience durable clinical benefit from this treatment and second-line chemotherapy shows dissatisfying results. We hypothesized that immune priming by CTLA-4 inhibition followed by immune boosting through stereotactic body radiation therapy (SBRT) could reinvigorate the anti-cancer immune response in metastatic NSCLC patients previously treated with anti-PD-(L)1 therapy.

Methods: The RAD-IO trial (NCT05401786) is a phase II, single-center, single-arm trial in patients with progressive stage IV NSCLC previously treated with anti-PD-(L)1. Patients were required to have at least two separate tumor lesions: one for SBRT and one out-of-field lesion for repeat biopsies and response measurement. Patients were treated with one dose ipilimumab (1mg/kg), followed by irradiation (3x8Gy) of one to four tumor lesions seven days later. One week after SBRT completion, patients started with PD-1 inhibition (cemiplimab 350mg every three weeks) for up to two years, until disease progression or unacceptable toxicity. Response evaluation using RECIST1.1 was performed every six weeks during the first 27 weeks and every twelve weeks thereafter. The primary endpoint was clinical benefit rate defined as complete or partial response (CR or PR), or stable disease (SD) lasting six months or longer after cemiplimab initiation. Primary endpoint was reached if ≥12 patients out of 54 showed clinical benefit. Secondary endpoints included progression-free survival (PFS), overall survival (OS) and safety according CTCAEv5.

Results: Between January 2023 and September 2024 we enrolled 54 patients, 35 were male (64.8%), median age was 63 years (range 43-81), 39 patients (72.2%) had adenocarcinoma, 23 patients (42.6%) had a PD-L1 negative tumor.

At data cut-off, January 31st 2025, median follow-up was 13.4 months (95%CI 8.2 - 16). The study reached its primary endpoint with clinical benefit in 13 patients (24.1%, 95%CI 13.5 - 37.6%): confirmed PR in six patients (11.1%) and SD ≥ six months in seven patients (13%). From start of cemiplimab, median PFS was 2.7 months (95%CI 1.5 - 4.2) for all 54 patients and 13.7 months (95%CI 8.6 - NA) for 13 patients with clinical benefit. Median OS was 14 months (95%CI 8.5 - NA).

Grade 3 or higher treatment-related adverse events (TRAEs) were seen in seven patients (13%). There were six grade 3 TRAEs: one patient with tracheal obstruction possibly related to SBRT, one adrenal insufficiency, one cholangitis, two lymphopenia and one ASAT/ALAT increase. There was one grade 5 acute kidney injury, probably CTLA-4 inhibition-related nephritis but without a biopsy to confirm this diagnosis.

Conclusions: In the RAD-IO trial, priming by CTLA-4 inhibition and immune boosting through SBRT followed by anti-PD-1 retreatment elicited clinical benefit in 24.1% of patients with advanced metastatic NSCLC who previously progressed on PD-(L)1 inhibition, thereby reaching the primary endpoint. No new safety signals were observed. Subgroup and translational analyses are ongoing to identify clinical and biological biomarkers in responding patients.

Introduction: EMPOWER-Lung 3 Part 2 (NCT03409614), a double-blind, placebo-controlled phase 3 study, demonstrated significant survival benefits with cemiplimab+chemotherapy versus chemotherapy in patients with previously untreated advanced NSCLC (aNSCLC) without EGFR/ALK/ROS1 aberrations. Cemiplimab is one of two checkpoint inhibitors with demonstrated efficacy in squamous and nonsquamous aNSCLC, both as monotherapy and with chemotherapy. Here, we report 5-year efficacy and safety outcomes.

Methods: Patients were randomized 2:1 to receive cemiplimab (350 mg every 3 weeks for up to 108 weeks) or placebo, plus 4 cycles of chemotherapy. Primary endpoint was overall survival (OS); secondary endpoints included safety, progression free survival (PFS), objective response rate (ORR), and duration of response (DOR). Patients were molecularly characterized via comprehensive genomic profiling of baseline tumor tissue or plasma.

Results: This study randomized 466 patients to cemiplimab+chemotherapy (n=312) or chemotherapy (n=154). After a median follow-up of 60.9 months, cemiplimab+chemotherapy continued to show significantly improved survival outcomes over chemotherapy. For cemiplimab+chemotherapy versus chemotherapy, respectively: median OS was 21.1 months versus 12.9 months (hazard ratio [HR]=0.662, 95% CI: 0.531-0.825, P=0.0002); median PFS was 8.2 months versus 5.5 months (HR=0.579, 95% CI: 0.467-0.718, P<0.0001); ORR was 43.6% versus 22.1%; and complete response was observed in 6.4% of patients (20/312) versus none, with median DORs of 16.4 and 7.3 months. Five-year OS probability was 19.4% (95% CI: 14.9-24.5%) for cemiplimab+chemotherapy versus 8.8% (4.8-14.4%) for chemotherapy. Efficacy was demonstrated in both histologies: for the squamous histology, median OS with cemiplimab+chemotherapy (n=133) was 22.3 months versus 13.8 months with chemotherapy (n=67; HR=0.678, 95% CI: 0.488-0.941); for non-squamous histology, median OS with cemiplimab+chemotherapy (n=179) was 19.4 months versus 12.4 months with chemotherapy (n=87; HR=0.615, 95% CI: 0.460-0.822). Among 327 (70.2%) patients with PD-L1 ≥1%, exploratory analyses showed median OS with cemiplimab+chemotherapy (n=217) was 24.0 months versus 12.1 months with chemotherapy (n=110; HR=0.537, 95% CI: 0.412-0.699). In total, 78% (362/466) of patients were mutation-evaluable; genomic profiling analysis indicated that the 3 most prevalent genes in the squamous group were TP53 (90%), CDKN2A (33%) and SOX2 (26%) and in the nonsquamous group TP53 (63%), KRAS (33%) and STK11 (24%). Of 312 patients in cemiplimab+chemotherapy arm, 66 (21.2%) completed protocol specified 2 years (108 weeks) of cemiplimab treatment and 5-year OS probability (including 2 years of treatment) for this subgroup was 56.0% (95%CI: 41.5-68.2). Grade ≥3 treatment-emergent adverse events occurred in 49.4% of patients receiving cemiplimab+chemotherapy and 32.7% receiving chemotherapy.

Conclusions: With 5-year follow-up, EMPOWER-Lung 3 continues to show durable long-term benefits with the use of cemiplimab+chemotherapy compared to chemotherapy as first-line therapy for aNSCLC. Safety profiles of cemiplimab+chemotherapy remained generally consistent with previously reported data.

MA11.01 Phase 1 Study of DLL3-Targeted CAR-T Cells Armored With dnTGFBR2 in Small-Cell Lung and Large-Cell Neuroendocrine Cancers

A.J. Schoenfeld[1], A. Chiappori[2], B. Creelan[2], R. Munker[3], M. Koneru[4], P. Schwarzenberger[4], S. Vahora[4], C. Davis[4], D. Geng[4], D. Xu[4], C. Wang[4], L. Xin[4], J. Sands[5], Z. Hao[3]
[1]Memorial Sloan Kettering Cancer Center, New York City/NY/USA ,[2]Moffitt Cancer Center, Tampa/FL/USA ,[3]Markey Cancer Center, Lexington/KY/USA ,[4]Legend Biotech USA Inc, Somerset/NJ/USA ,[5]Dana Farber Cancer Institute, Boston/MA/USA

Introduction: DLL3 is a validated target in small-cell lung cancer (SCLC) and high-grade neuroendocrine tumors. LB2102 comprises autologous DLL3-targeted CAR-T cells armored with dominant-negative TGFBR2, enabling them to overcome tumor-mediated immunosuppression. We present preliminary results from a phase 1 study of LB2102 as a one-time therapy in patients with relapsed or refractory SCLC or LCNEC.

Methods: This 3+3 dose-escalation study assesses safety, dose-limiting toxicities (DLTs), and efficacy of LB2102 across 7 dose-levels (0.3-16.0×10E6 CAR+T cells/kg) following fludarabine and cyclophosphamide lymphodepletion.

Results: As of March 5, 2025, of 17 enrolled patients, 12 (average 86% DLL3 expression at baseline) received LB2102 across 4 dose levels. Median age was 55 y (range, 20-68 y) with 2 median prior lines of therapy (range, 1-5). Ten patients had SCLC, 2 had LCNEC, and 11 received bridging therapy. Median time from apheresis to LB2102 was 87.0 days and follow up was 120.5 days. Seven patients experienced treatment (LB2102)-related adverse events (TRAEs) (2 Grade ≥3, see Table 1). Serious adverse events occurred in 5 patients after LB2102, 1 attributed to LB2102. Two patients developed Grade 1 cytokine-release syndrome. No DLTs or neurotoxicity were reported. Per RECIST1.1, median best overall change in tumor size was -19.1% (range across dose-levels, see Figure 1). Among 10 evaluable patients, the objective response rate was 20% and the disease-control rate was 70%. Pharmacokinetics suggest greater CAR-T expansion in peripheral blood at higher dose levels, with a median Cmax of 694 copies/µgDNA (range, 45.6-2260) and median Tmax of 15 days (range, 10-29) at dose level 3.

Conclusions: LB2102 was well tolerated, with no DLTs observed up to dose-level 4. A dose-dependent efficacy signal was observed; higher dose levels were associated with increased response rates, CAR-T expansion, and response duration. Evaluation at higher dose levels is warranted to assess LB2102's therapeutic potential.

Table 1: Summary of Adverse Events

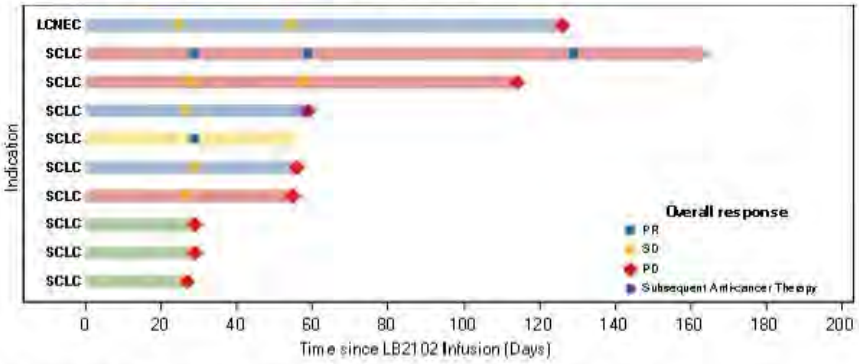
Dose levels	DL1 0.3×10⁶ CAR+T cells/kg (N=3) n (%)	DL2 1.0×10⁶ CAR+ T cells/kg (N=3) n (%)	DL3 2.0×10⁶ CAR+ T cells/kg (N=3) n (%)	DL4 4.0×10⁶ CAR+ T cells/kg (N=3) n (%)	Total (N=12) n (%)	
					Any Grade	Grade≥3
TEAE related to LB2102 (TRAE)	2 (66.7)	2 (66.7)	1 (33.3)	2 (66.7)	7 (58.3%)	2 (16.7)
Anemia	0	2 (66.7)	0	1 (33.3)	3 (25.0%)	2 (16.7)
CRS	0	0	1 (33.3)	1 (33.3)	2 (16.7%)	0
Hypotension	1 (33.3)	1 (33.3)	0	0	2 (16.7%)	0
Nausea	2 (66.7)	0 (0)	0	0	2 (16.7%)	0
Neutrophils/WBC decreased	0	2 (66.7)	0	0	2 (16.7%)	2 (16.7)
TRAEs resolved within 28 days of LB2102/total number of TRAEs (%)	1/3 (33.3%)	8/8 (100%)	2/2 (100%)	0/3 (0%)	11/16 (68.8%)	7/7 (100%)
Any serious TEAE	1 (33.3)	1 (33.3)	1 (33.3)	2 (66.7)	5 (41.7%)	3 (25.0)
Serious TRAEs	0	0	0	1 (33.3)	1 (8.33%)	0
CRS	0	0	0	1 (33.3)	1 (8.33%)	0
AESIs	0	0	0	0	0	0
Any DLT	0	0	0	0	0	0

AESI, adverse event of special interest (defined as CRS Grade ≥ 3, any-grade neurotoxicity, infection Grade ≥ 4, or new primary malignancy); CRS, cytokine release syndrome; DL, dose level; DLT, dose-limiting toxicity (defined as Grade ≥ 3 CRS, Grade ≥ 3 neurotoxicity, Grade ≥ 3 allergic reaction related to cell infusion, Grade 5 hematologic, or Grade ≥ 3 non-hematologic toxicity); TEAEs, treatment-emergent adverse events that started or worsened after LB2102 infusion; TRAEs, treatment-emergent adverse events deemed related to LB2102 infusion; WBC, white blood cell count

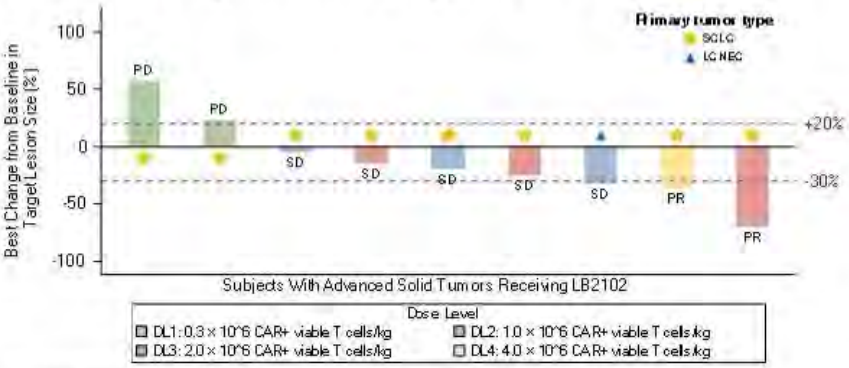
Notes: Percentages are based on the number of patients in the Safety Analysis Set (N) unless otherwise indicated. The number of patients (n) with at least 1 AE within each preferred term is presented. Only TRAEs in ≥ 2 overall patients are presented.

Figure 1: Summary of Responses and Durations

A. Response and Duration of Response by Indication



B. Best Percent Change from Baseline in Target-tumor Lesion Size



PD, progressive disease; PR, partial response; SD, stable disease

Notes: One patient who received DL1 had non-measurable disease prior to lymphodepleting chemotherapy; RECIST1.1 criteria data are pending for 2 patients.

Introduction: Tifcemalimab, a humanized IgG4 monoclonal antibody against B and T lymphocyte attenuator (BTLA), has shown preliminary anti-tumor activities in combination with toripalimab (anti-PD-1 antibody) as a later-line treatment for patients with lung cancer. We further conducted a multi-cohort phase Ib/II study (NCT05664971) to evaluate the safety and efficacy of tifcemalimab combined with toripalimab and chemotherapy in patients with advanced lung cancer. Here, we report the preliminary results from the extensive-stage small cell lung cancer (ES-SCLC) cohort.

Methods: Patients with ES-SCLC who had not received systemic anti-tumor therapy were administrated with tifcemalimab 200 mg in combination with toripalimab 240 mg and etoposide 100 mg/m2 plus carboplatin AUC 5 or cisplatin 75 mg/m2 intravenously every 3 weeks until disease progression, intolerable toxicity, or completion of 2-year of tifcemalimab and toripalimab. Primary endpoints included safety and objective response rate (ORR) assessed by investigators per RECIST v1.1.

Results: From Jul 12, 2023 to Dec 6, 2023, a total of 44 patients were enrolled with the median age being 63 (range 48-73) years and 84.1% (37/44) being male. The median follow-up duration was 15.28 months. Among 43 evaluable patients, 37 partial responses and 6 stable diseases were observed, the ORR and disease control rate were 86% and 100%, respectively. Median progression-free survival was 5.7 months (95% CI 4.8, 7.0). Median overall survival (OS) was not reached yet and the 15-month OS rate was 63.5%. Forty-three (97.7%) patients experienced treatment-emergent adverse events (TEAEs), grade ≥ 3 TEAEs occurred in 40 (90.9%) patients, and the most common (≥20%) grade ≥ 3 TEAEs included neutrophil count decreased (65.9%), white blood cell count decreased (25.0%), and platelet count decreased (25.0%). Three (6.8%) patients discontinued tifcemalimab due to TEAE. Twenty (45.5%) patients experienced immune-related AE (irAEs), among whom 7 (15.9%) reported grade 3 or higher irAEs. Serious adverse events occurred in 19 (43.2%) patients. TEAE leading to death occurred in 1 (2.3%) patient, which was not considered related to any treatment.

Conclusions: Tifcemalimab in combination with toripalimab and chemotherapy showed promising antitumor activities with a manageable safety profile as a first-line treatment for patients with ES-SCLC.

Introduction: IMforte (NCT05091567) demonstrated significant and clinically meaningful improvements in independent review facility-assessed PFS (stratified HR, 0.54; 95% CI, 0.43-0.67) and OS (stratified HR, 0.73; 95% CI, 0.57-0.95) with lurbinectedin + atezolizumab vs atezolizumab for 1L maintenance treatment of ES-SCLC. The combination was generally well tolerated with a manageable safety profile. The incidence of all AE categories was higher in the experimental arm, which was not unexpected given the combination regimen and longer treatment exposure (median treatment duration: lurbinectedin + atezolizumab, ≈4.2 months; atezolizumab, 2.1 months). Notably, febrile neutropenia incidence was low (1.7%) in the combination arm with mandatory G-CSF prophylaxis. We present additional safety data on treatment discontinuations due to AEs and on neutropenia, further evaluating the tolerability of the combination.

Methods: Eligible patients with ES-SCLC without PD after 1L induction therapy with atezolizumab, carboplatin and etoposide were randomised 1:1 to receive maintenance treatment q3w with lurbinectedin 3.2 mg/m2 + atezolizumab 1200 mg (with G-CSF) or atezolizumab until PD, or unacceptable toxicity. Safety was assessed from start of maintenance treatment.

Results: Patients received lurbinectedin + atezolizumab (n=242) or atezolizumab (n=240; clinical cutoff: 29 July 2024). Overall, the safety profile of lurbinectedin + atezolizumab (median safety follow-up, 6.4 months) reflected the known risks of both drugs; no new safety signal was identified. In the lurbinectedin + atezolizumab arm, 12 (5.0%) and 6 patients (2.5%) discontinued lurbinectedin and atezolizumab, respectively, due to AEs; in the atezolizumab arm, AEs resulted in discontinuation in 8 patients (3.3%). The majority of treatment discontinuations due to AEs occurred within the first 3 months of treatment (Table). Most patients discontinued treatment due to PD (≳80% both arms). Rates of Grade 3/4 neutropenia were 4.5% with lurbinectedin + atezolizumab and 0.4% with atezolizumab; febrile neutropenia occurred in 1.7% (including 1 fatal event) and 0 patients, respectively. Fatal AEs occurred in 12 patients (5.0%) with lurbinectedin + atezolizumab and in 6 (2.5%) with atezolizumab.

Conclusions: Lurbinectedin + atezolizumab was generally well tolerated, with low rates of AE-related discontinuations, although higher than with atezolizumab. High-grade neutropenia and febrile neutropenia with lurbinectedin + atezolizumab occurred at lower rates than with previous clinical experience with lurbinectedin, possibly related to the primary G-CSF prophylaxis in IMforte. Although fatal AE rates were numerically higher with lurbinectedin + atezolizumab, no unexpected findings attributable to the combination regimen were identified. Overall, the combination demonstrated a manageable safety profile, with no new safety signals.

Table: AEs* resulting in discontinuation by duration

	Lurbinectedin + atezolizumab (n=242)		Atezolizumab (n=240)

MA11.05 Comparative Outcomes of Lobectomy and Sub-Lobar Resections in Pulmonary Carcinoids: A Multicentre Retrospective Cohort Study

M. Dziedzic[1], M. Pawlica[2], K. Chrzanowska[2], S. Antoniak[1], P. Ciepiałowska[1], M. Cackowski[3]
[1]Medical University of Gdańsk, Gdańsk/PL ,[2]Medical University of Warsaw, Warsaw/PL ,[3]National Research Institute of Chest Diseases, Warsaw/PL

Introduction: Pulmonary carcinoids (PCs) represent a rare group of neuroendocrine tumors (NETs) occurring in the respiratory tract, distinguished by their specific biological features and clinical behavior. Despite the advancements in endobronchial therapies and immunochemotherapy, surgical resection remains the gold standard for first-line treatment. However, there is limited evidence comparing the outcomes of sub-lobar resections versus lobectomy.

Methods: The patient data was retrospectively obtained from the Polish Lung Cancer Study Group (PLCSG) database, which compiles records of surgically treated patients from nearly 30 thoracic centers throughout Poland. The study included those with typical or atypical carcinoids confirmed by histopathology who underwent radical surgical resection between 2007 and 2023 and had complete clinical data available.

Results: The study included 2467 patients. The majority were female (69.8% vs. 30.2%) and non-smokers (62.3% vs. 37.7%), with a median age of 61 years. Typical carcinoids were significantly more prevalent than atypical (75.8% vs. 24.2%). All of the patients were staged according to the 9th edition of the tumor-metastases-nodes (TNM) staging, and the most common stages were IA and IB, with 67.4% and 18.9%, respectively. The T stages were assessed, and stages pT1 (71.4%) and pT2 (22.1%) were substantially the most frequent. In the majority of the patients, lymph node involvement was absent (91.3% vs 8.7%), and among those with involvement (8.7%), stage pN1 was the most common (5.5%). Metastases were acknowledged only in 1.2%, and all of the patients were stage M1. The surgical treatment included lobectomy, wedge resection, segmentectomy, and pneumonectomy, with respective distributions of 82.7%, 7.9%, 6.1%, and 3.3%. The 5-year overall survival rates (OSR) were evaluated across the entire study population and were 93.1% (95% CI: 94.32-91.92) for lobectomy, 90.4% (95% CI: 96.13-85.00) for segmentectomy, 87.6% (95% CI: 93.06-82.49) for wedge resection, and 78.2% (95% CI: 87.95-69.50) for pneumonectomy. When the study cohort was divided into typical and atypical carcinoids, lobectomy and segmentectomy showed the highest overall survival rates in the atypical group with 86.8% and 72.4%, respectively (p<0.0001). In contrast, among patients with typical carcinoids, there were no statistically significant differences in overall survival rates between sub-lobar resections and lobectomy.

Conclusions: This retrospective multicenter study compares the efficacy of lobectomy and sub-lobar resections in the treatment of pulmonary carcinoids. The results demonstrate the superiority of lobectomy over segmentectomy, showing better 5-year OSR in the atypical carcinoid subgroup.

Introduction: To gain insights into the evolutionary processes of small cell lung cancer (SCLC), it is important to analyze the primary tumor and multiple metastatic lesions in different organs from the same patient. This is particularly relevant, as therapeutic resistance may be associated with increased tumor heterogeneity and subtype plasticity. Nevertheless, acquiring representative tumor tissue specimens remains difficult in SCLC, and performing multiple biopsies is invasive and often clinically impractical. Here, we investigated inter-lesion SCLC heterogeneity and plasticity with regard to protein expression landscape and molecular subtypes, identifying stably expressed therapeutic targets across distinct metastatic sites.

Methods: Representative tissue samples from primary tumors, metastatic lesions, and corresponding non-tumorous control samples, were obtained through our multicenter SCLC rapid research autopsy (RRA) program. All RRAs were conducted within four hours of the patient's death by a dedicated multidisciplinary team. The number of tumorous specimens retrieved from distinct sites per a single patient ranged from 6 to 14. Multiomic profiling of the acquired fresh, snap-frozen, and formalin-fixed specimens was achieved by mass spectrometry (MS)-based proteomics (nLC-MS/MS), RNAseq (KAPA Hyper RNA with Riboerase) and immunohistochemistry (IHC). Specific pathways linked to tumor content differences were analyzed, confirming the histological pattern of the samples. Biostatistical and bioinformatics approaches were applied to evaluate inter-lesion tumor heterogeneity and to identify differentially and stably expressed molecules, as well as metastasis site-specific alterations.

Results: We collected 194 tumor specimens and 60 matched non-tumorous controls from 23 SCLC patients. Tumor sites included lung, brain, brainstem, cerebellum, liver, adrenal glands, peritoneum, pleura, pericardium, skin, spleen, and lymph nodes. On average, 19354 transcripts (TPM>0) and 7786 protein groups were quantified per sample. In general, clinically relevant SCLC-related proteins and therapeutic targets exhibited a moderate to high degree of inter-lesion heterogeneity. Subsequent IHC analyses validated the observed high inter-lesion proteomic heterogeneity. We identified 27 stably expressed novel therapeutic targets showing tumor-specificity (adj.p<0.05 & FC>1.5) and a low degree of inter-lesion variability (pooled MAD < 15%) in their expression pattern. Besides SCLC-A, -N, -AN, -P, and -QN, IHC analyses distinguished a unique subtype with high ASCL1 expression and an inflamed phenotype (SCLC-A-inflamed). In 85% of the examined patients, the dominant molecular subtype differed across metastatic sites, as per IHC. Notably, significant subtype intra-tumoral heterogeneity (intralesion spatial sectioning distance: 40 µm) was identified in 59% of examined cases.

Conclusions: Several known clinically relevant proteins and therapeutic targets have heterogeneous expression profiles across tumor sites within a SCLC patient. Molecular subtypes show both intratumoral and inter-lesion variability. The newly identified stably expressed proteins are potential novel therapeutic targets that warrant further therapeutic validation.

MA11.08 Longitudinal Circulating Tumor DNA Dynamics Predict Therapeutic Efficacy in ES-SCLC Treated With Immunotherapy

M. Xie[1], L. Liu[1], X. Chu[1], C. Su[1]
[1]Shanghai Pulmonary Hospital & Thoracic Cancer Institute, Tongji University School of Medicine, Tongji University, Shanghai/CN

Introduction: While immune checkpoint inhibitors (ICIs) combined with platinum-etoposide chemotherapy improve outcomes in extensive-stage small-cell lung cancer (ES-SCLC), the prognostic role of longitudinal circulating tumor DNA (ctDNA) dynamics remains underexplored. This phase II trial investigates ctDNA's association with therapeutic response.

Methods: In this single-arm prospective study (ChiCTR2000038354), treatment-naïve ES-SCLC patients received sintilimab plus chemotherapy. Serial plasma samples were collected for ctDNA analysis using next-generation sequencing. Maximum somatic allele frequency (MSAF), blood intratumor heterogeneity (bITH), and log10-transformed haploid genome equivalents/mL (log10hGE) were correlated with progression-free survival (PFS) and overall survival (OS).

Results: This study included 43 patients who were evaluable for treatment response, with 42 baseline blood samples and 37 longitudinal on-treatment blood samples collected. Patients were stratified into durable clinical benefit (DCB) and non-durable benefit (NDB) groups based on PFS exceeding 6 months. The NDB group demonstrated higher maximum somatic allele frequency (MSAF). Patients with lower baseline MSAF demonstrated significantly improved progression-free survival (PFS: HR=0.45, 95%CI 0.2-1, p=0.045) and overall survival (OS: HR=0.11, 95%CI 0.01-0.81, p=0.008). Univariate and Multivariate Cox regression confirmed baseline MSAF as an independent prognostic factor for both PFS and OS. Longitudinal analysis revealed dynamic ctDNA changes predictive of therapeutic outcomes: ΔMSAF independently correlated with OS in multivariate analysis (HR=0.05, 95%CI 0-0.97, p=0.048). Post-treatment reductions in blood intratumor heterogeneity (ΔbITH) and log10-transformed haploid genome equivalents/mL (Δlog10hGE) further stratified clinical outcomes. Patients with greater ΔbITH reduction showed extended PFS (8 vs 6.1 months; HR=2.47, p=0.023), and those with higher Δlog10hGE decreases achieved longer PFS (7.3 vs 5.7 months; HR=3.17, p=0.011). Both bITH and log10hGE metrics exhibited progressive decline during treatment, mirroring therapeutic response.

Conclusions: This study identifies ctDNA dynamics as pivotal biomarkers for sintilimab-chemotherapy in ES-SCLC. Baseline MSAF independently predicts survival, with lower values indicating superior PFS and OS. Early reductions in ΔMSAF, ΔbITH, and Δlog10hGE stratify therapeutic response, while progressive declines in bITH and ctDNA load (log10hGE) reflect clinical benefit. Our results bridge ctDNA dynamics with clinical outcomes, offering a non-invasive approach to optimize SCLC immunotherapy management. Randomized trials are needed to validate these biomarkers' utility.

PT1.01.01 Large Language Models to Extract Smoking History From Clinical Notes in EHR to Evaluate Lung Cancer Surveillance Strategies

I. Luo[1], A. Graber-Naidich[1], R. Kaushik[1], G.M. Nieda[1], E. Choi[2], V.Y. Ding[1], F. Gunturkun[1], M. Satoyoshi[1], A. Bhat[1], T. Chen[3], M. Zhang[1], T. Lee[1], C.C. Su[1], T.J. [1]Stanford University, Palo Alto/CA/USA ,[2]Weill Cornell Medicine, New York/NY/USA ,[3]Sutter Health, Palo Alto/CA/USA ,[4]Indian Institute of Technology Roorkee, Roorkee/IN

Introduction: Accurate smoking documentation in electronic health records (EHRs) is essential for lung cancer (LC) risk assessment, screening, and monitoring. However, smoking data are often missing or inconsistently recorded due to recall bias and reporting errors. Large language models (LLMs) offer a promising solution for interpreting clinical narratives, yet their effectiveness in extracting detailed smoking data remains unexplored. This study aimed to develop a framework leveraging LLMs and rule-based smoothing to extract and harmonize longitudinal smoking data, with applications in LC surveillance.

Methods: We evaluated three generative AI models (Gemini-1.5-Flash, PaLM-2 Text-Bison, GPT-4) against encoder-based models (ClinicalBERT, BlueBERT) using 1,683 manually-annotated clinical notes from 500 patients across academic (Stanford) and community (Sutter Health) healthcare systems. Models extracted seven smoking variables, including status, duration, quit date, and pack-years. To curate comprehensive longitudinal smoking data, the best-performing model (Gemini-1.5-Flash) was deployed on an independent set of 80,037 notes from 4,988 Stanford LC patients. Rule-based smoothing integrated the AI-extracted variables with structured EHRs. We assessed the clinical utility of the curated smoking data by evaluating various post-diagnosis surveillance strategies in these patients.

Results: Generative AI models outperformed encoder models in extracting smoking status from notes (accuracy on hold-out set: 95.6%-97.5% vs. 69.5%-74.2%). Among generative models, Gemini-1.5-Flash achieved the highest average accuracy across 7 variables (Table-1), ranging from 94.1% for packs-per-day to 99.6% for cessation-age. External validation (500 notes) in Sutter confirmed Gemini-1.5-Flash's generalizability with 98.3% average accuracy across variables. Analysis of the curated smoking data showed that a comprehensive risk-model-based surveillance strategy utilizing both smoking and clinical data outperformed NCCN guidelines based solely on clinical data in identifying second malignancies (Figure-1).

Conclusions: This study highlights the potential of generative AI to improve the quality and utility of smoking documentation in EHRs, facilitating evaluation of effective LC surveillance and broader clinical applications.

Table-1. Comparative performance of three generative AI models for smoking variable extraction using Stanford hold-out test set (236 notes) and Sutter Health external validation cohort (500 notes). Shading represents relative model performance: green for high accuracy, white for moderate, and red for low.

	Model	Overall	Smoking Status	Duration	Age at cessation	Year of cessation	Years since cessation	Pack year	Pack per day
Stanford	Gemini 1.5 Flash	96.5%	95.6%	94.9%	99.6%	97.9%	95.4%	97.9%	94.1%

PT1.01.02 Temporal Analysis of Smoking Profiles in Brazil Among Lung Cancer Patients and the Impact of 25 Years of Public Policies

B.B.d. Rezende[1], L. Assumpção[2], S. Jamnik[1], I. Santoro[1], L. Lauricella[3], R. Terra[4]
[1]Federal University of São Paulo, São Paulo/BR ,[2]State University of Rio de Janeiro, Rio de Janeiro/BR ,[3]Universitu of São Paulo, São Paulo/BR ,[4]Hospital Israelita Albert Einstein, São Paulo/BR

Introduction: Smoking is the main risk factor for lung cancer. Studies indicate that if the current pattern of tobacco consumption in Brazil persists, lung cancer cases are expected to increase by 65% and mortality by 74% by 2040. Over the past 40 years, Brazil has invested in public policies aimed at smoking cessation. This study aims to analyze temporal changes in the Brazilian smoking profile over the past 25 years and the impact of public measures implemented in the last 40 years.

Methods: This is a retrospective cohort study of 2,488 lung cancer patients from three hospital institutions in São Paulo, between 1999 and 2024. Variables analyzed included sex and smoking status. Statistical tests were applied according to data type and distribution (Wilcoxon, Shapiro-Wilk, Kruskal-Wallis, chi-square, and Cochran-Armitage trend tests).

Results: In 1999, the probability of having lung cancer and being an active smoker was 50.91%, decreasing to 20% in 2016 and 12.33% in 2024. The probability of a person having lung cancer and being a non-smoker increased from 6.34% (1999) to 34.24% in 2024. There was a gradual increase, with significant jumps in the years 2004 (19.82%), 2007 (26.52%), 2020 (30.57%), 2023 (33.45%), and 2024 (34.24%), with a peak in smoking cessation observed in 2006 (57.11%). The probability of having lung cancer and being a former smoker rose from 41.25% (1999) to 53.24% (2024). The percentage of active smokers among lung cancer patients was similar between sexes (21.30% in men vs. 20.19% in women). However, among non-smokers, females predominated (37.32% vs. 12.88% in men). Among those who quit smoking after diagnosis, men were the majority (65.32%). The distribution of smoking status between sexes was statistically different ($p < 0.0001$), indicating that smoking patterns vary between men and women. In 1999, the probability of being a non-smoking man with lung cancer was only 2.78% ($p = 0.03$). In 2024, this probability increased to 28.10% ($p = 0.001$). In women, this trend was not statistically significant.

Conclusions: Among lung cancer patients, there has been a decrease in the number of active smokers over time. The probability of being a lung cancer patient who does not smoke has increased. There has also been an increase in the likelihood of quitting smoking after diagnosis.

Women with lung cancer tend to be non-smokers more often than men. However, among smokers, men are more likely to quit smoking after diagnosis than women.

PT1.01.03 IMPRINT-Lung: Single-Arm, Multi-Center Phase II Trial of Immunotherapy With Pembrolizumab for Interception of High-Risk Lung Nodules

J.J. Zhang[1], M. Godoy[1], V. Velcheti[2], D. Sterman[2], A. Tam[1], R. Rajaram[1], H. Tran[1], R. Keith[3], S. Heeke[1], H. Chen[1], B. Carter[1], M. Antonoff[1], E. Ostrin[1], X. Le[1], C. Gay[1], M.V. Negrao[1], J.V. Pozadzides[1], S.H. Lin[1], L. Byers[1], N. Vokes[1], T. Cascone[1], D.L. Gibbons[1], B. Zhang[1], H. Araujo[1], C. Lu[1], G. Blumenschein[1], D. Rice[1], G.L. Walsh[1], J. Chang[1], Z. Liao[1], W.L. Hofstetter[1], R. Mehran[1], A. Vaporciyan[1], I. Wistuba[1], J. Wu[1], J.J. Lee[1], J.V. Heymach[1]
[1]MD Anderson Cancer Center, Houston/TX/USA ,[2]New York University, New York/NY/USA ,[3]University of Colorado, Dever/CO/USA

Introduction: The widespread implementation of lung cancer screening and the advent of high-resolution CT for diagnostic imaging have led to a significant increase in the detection of indeterminate pulmonary nodules (IPNs). If persistent, many of these IPNs are lung cancer precursors. While some IPNs can be resected with minimal morbidity, the cost-effectiveness and necessity of surgical resection remain subjects of debate. Additionally, multifocality is a common occurrence, further complicating surgical management. Previous studies have demonstrated that lung cancer precursors exhibit a simpler molecular landscape and a more intact immune response than invasive lung cancer. Furthermore, adaptive immune evasion—such as PD-L1 upregulation—emerges at the precursor stage. These findings led to the development of the IMPRINT-Lung trial, a single-arm, multi-center phase II study evaluating anti-PD-1 pembrolizumab for the interception of high-risk lung nodules.

Methods: Patients with persistent high-risk pulmonary nodules—defined as nodules that show no evidence of regression on at least two CT scans taken three months apart, with a predicted malignancy risk >10% based on the Brock model for those without a personal history of lung cancer, or >5% for those with localized lung cancer who have completed standard-of-care therapy—are eligible to receive pembrolizumab at a dose of 200 mg intravenously every three weeks for up to four doses. CT scans are performed at 6 weeks, 12 weeks, and 6 months to assess treatment response. The primary endpoint is therapeutic outcomes at 6 months post-pembrolizumab treatment, evaluated using modified RECIST (mRECIST) criteria, which account for both solid and ground-glass opacity components. Additionally, radiologic images undergo 3D volumetric analysis, and peripheral blood samples collected at baseline (prior to treatment initiation), 3 weeks, and 6 months after the first dose of pembrolizumab undergo T cell receptor (TCR) sequencing, cytokine profiling, single-cell RNA sequencing (scRNA-seq), and plasma cell-free DNA (cfDNA) methylation profiling using the TEEM-seq methodology.

Results: A total of 40 patients received at least one dose of pembrolizumab and all patients have completed 6 months follow up. The treatment was generally well tolerated. Two patients experienced Grade 3 toxicities unrelated to pembrolizumab (retinal detachment, n=1; hypertension, n=1), while three patients developed Grade 2 toxicities that were either possibly related or related to pembrolizumab (pruritus, n=1; hypothyroidism, n=2). All remaining toxicities were Grade 1. At the 6-month post-treatment time point, 36 patients were evaluable. Two patients had progressive disease due to the emergence of new pulmonary nodules. Among the remaining 34 patients, only one met the criteria for partial response (-34% from baseline) per mRECIST criteria. However, 18 patients exhibited some degree of lung nodule shrinkage, with a median reduction of -3% and an average reduction of -5%. Notably, all 40 patients had experienced nodule enlargement before pembrolizumab treatment. Radiomics analysis and peripheral blood biomarker profiling are currently ongoing.

Conclusions: Pembrolizumab has demonstrated a favorable safety profile and preliminary evidence of efficacy in treating patients with persistent high-risk lung nodules. Intercepting precancerous high-risk lung nodules by reprogramming the tumor immune microenvironment remains a promising strategy for lung cancer prevention.

PT1.02.01 Targeting NOX1/4-YAP/TEAD-CD47 Axis Promotes Macrophage Phagocytosis and Potentiates Radiotherapy Antitumor Efficacy in NSCLC

J. Wang[1], Y. Kui[1], X. Dong[2]
[1]Cancer Center, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China, hubei/CN ,[2]Cancer Center, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan/CN

Introduction: Radiotherapy, as a crucial treatment style of non-small cell lung cancer (NSCLC), could lead to form immunosuppressive microenvironment by regulating the expression of immune molecules, such as phagocytosis checkpoints. Anti-phagocytosis checkpoint CD47 universally expresses on tumor cells. Although anti-CD47 treatment is a promising immunotherapy manner, the treatment has serious blood toxicity because that normal blood cells also express CD47. Therefore, targeting specially CD47 on tumor cells without on normal blood cells can promote phagocytosis function of macrophages and enhance radiosensitivity.

Methods: A drug array was used to recognize compounds that can suppress radiotherapy-induced CD47 expression in NSCLC via flow cytometry assay. THP-1-derived macrophages were co-cultured with lung tumor cells treated with NOX1/NOX4 inhibitor (GKT137831, GKT). The tumor-bearing mouse models were treated with GKT and radiotherapy to further analysis tumor environment by flow cytometry.

Results: Radiotherapy increases CD47 expression on lung cancer cells by radiation dose and time dependent style. The drug screenings identified NOX1/NOX4 inhibitor GKT137831 could inhibit baseline expression of CD47 and radiation-induced CD47 upregulation in NSCLC. Knockdown of NOX1 and NOX4 respectively could downregulate CD47. Moreover, both knockdown of NOX1 and NOX4 has the strongest inhibition effect. The co-culture experiment suggested that GKT could promote macrophages to phagocytose lung cancer cells and also enhanced radiotherapy-induced phagocytic impairment. The mechanism analysis of RNA-seq data revealed that tumor cells treated with GKT is associated with YAP1/TEAD4 hippo signal pathway to inhibit CD47 expression. In mouse models, GKT enhance radiosensitivity through a macrophages-dependent mechanism without increasing blood toxicities.

Conclusions: This study unveils a novel mechanism which regulates basal CD47 expression and radiotherapy-induced CD47 upregulation in tumor cells. Targeting NOX1/NOX4-YAP1/TEAD4 signaling could suppress CD47 expression, resulting in promoting phagocytosis function of macrophages without blood toxicity and improving the anti-tumor efficacy of radiotherapy in NSCLC.

PT1.02.02 Novel Organoid Models of Patient-Derived Lung Cancer in Decellularized Mouse Lung Tissue

R. Navab
Princess Margaret Cancer Centre, Toronto/ON/CA

Introduction: The extracellular matrix (ECM) plays a crucial role in cancer biology, including tumor progression and response to therapeutics. Current organoid models mostly rely on Matrigel, a mouse tumor cell-derived matrix, which may not accurately represent the ECM of patient tumors. Therefore, there is a strong rationale for developing additional three-dimensional (3D) ex vivo models for cancer research. This study focuses on developing such a model for lung cancer research using decellularized lungs from normal mice (DCL).

Methods: Cellular compartments of C57/Bl6 mouse lungs were removed through a decellularization procedure. To model different experimental scenarios, we generated four distinct decellularized lung models by seeding: (1) established lung (A549) and breast (MCF7, MDA-MB231) cancer cell lines (CL); (2) total and EpCAM sorted cell population isolated from patient-derived xenografts (PDX) (XDC); (3) organoids established from PDX models (XDO); and (4) total cell population obtained from resected primary lung cancer tumors (PLC). Seeded DCL samples were maintained in culture for 30 days. Tumor growth was represented by 2-dimensional (D) surface coverage area of DCL sections measured by the HALO software (Indica Labs, Albuquerque, NM). Tumor cells were labeled with mCherry to quantify growth rates. To compare XDC models with their corresponding PDX tumors, RNA sequencing data was analyzed alongside proteomics data from 18 PDX models to identify target genes and proteins associated with successful growth in XDC model.

Results: Tumor cell establishment rates in DCL models were: 100% (4/4) for CL, XDC (EpCAM sorted cells) and XDO groups, 57% (16/28) for XDC (total cells), and 18.7% (6/32) for PLC. Growth analysis of two non-small cell lung cancer (NSCLC) XDO models expressing mCherry (XDO344mCh and XDO377mCh) demonstrated significant proliferation over 30 days ($P = 0.006$ and $P = 0.0018$, respectively). Histological analysis of successful models revealed ECM deposition, with new eosinophilic collagen-like material in DCL, suggesting new ECM production by tumor cells. Growth rates were highest in CL, XDC (EpCAM sorted cells) and XDO models, likely due to the purity of tumor cells derived from cell lines and PDX tumors, as well as reduced abundance of non-tumor cell populations. We also used the XDC137 (EpCAM sorted cells) model generated from PHLC137 lung PDX with EGFR exon 19 deletion to investigate drug response. The tumor cells in the 3D-XDC model recapitulated the corresponding PDX137's sensitivity to EGFR tyrosine kinase inhibitors. Ongoing studies aim to identify XDC derived proteins to elucidate their roles in tumor growth within DCL models.

Conclusions: Decellularized mouse lung tissue provides a microenvironment that supports the growth of primary NSCLC cells in 3D matrix as scaffold. This new platform may complement existing organoid platform to study lung cancer in matrix stroma that more closely mimic the patient tumors.

PT1.02.03 GBC-11004: An AI-Driven Novel Kinase Target With Potential to Overcome Osimertinib Resistance in NSCLC

J. Ryu
Gradiant bioconvergence, Seoul/KR

Introduction: Osimertinib resistance in non-small cell lung cancer (NSCLC) presents a significant clinical challenge, driven by a variety of mechanisms that complicate patient outcomes. Conventional next-generation sequencing (NGS) analysis methods often fall short in identifying effective therapeutic targets due to the complexity and heterogeneity of resistance mechanisms.

Methods: We have developed an artificial intelligence (AI)-driven target discovery platform designed to identify novel and effective drug target genes capable of overcoming Osimertinib resistance in NSCLC, surpassing the constraints of conventional NGS analysis. This platform integrates three key components: deep learning (G-TAC), statistical significance testing (G-SET), and a large language model (G-LAT). G-TAC and G-SET work together to identify and stratify genes based on their responsiveness to Osimertinib and tumor-specific expression profiles. G-LAT assesses these genes based on publications and clinical trials to ensure novelty and efficacy of the identified targets.

Results: A novel kinase target, designated GBC-11004, emerged as one of the top-ranked candidates, exhibiting overexpression in patient-derived organoids (PDOs) resistant to Osimertinib. To assess the functional relevance of GBC-11004, target validation was conducted using PDOs and CRISPR/Cas9-based gene editing. Gene editing in Osimertinib-resistant PDOs resulted in a significant reduction in cell viability, which correlated with an increased indel frequency. Furthermore, preliminary IC50 analyses of compounds targeting GBC-11004 were performed to optimize lead compounds. Notably, combination therapy (Osimertinib + GBC-11004 inhibitor) demonstrated significantly improved sensitivity compared to Osimertinib monotherapy in multiple resistant PDO models.

Conclusions: These findings highlight the potential of GBC-11004 as a novel therapeutic target for overcoming Osimertinib resistance in NSCLC, reinforcing the robustness of the PDO-based AI-driven platform for target discovery in identifying high-priority, novel therapeutic targets.

PT1.02.04 Mapping Gene-Environment Interactions Driving Small Cell Lung Cancer (SCLC) Initiation in Human Airway Organoids

A. Marco[1], N. Candeli[1], N. Hou[2], R. Passannante[1], J.L. McFaline-Figueroa[2], T. Dayton[1]
[1]EMBL, Barcelona/ES ,[2]Columbia University Biomedical Engineering, New York/NY/USA

Introduction: Small cell lung cancer (SCLC) accounts for up to 15% of all lung cancers and is the most fatal type, with a 5-year overall survival of ~6%. SCLC's etiology involves genetic alterations, such as the near-universal loss of TP53 and RB1, and environmental exposures like smoking or air pollution. Patients with SCLC often present with metastasized disease, preventing the use of human samples to study the early stages of the disease. Therefore, it is not well understood how genetic and environmental factors can drive the malignant transformation of pulmonary neuroendocrine cells (PNECs) into poorly differentiated cells with fast growth and rapid metastatic spread.

Methods: To overcome the lack of human models of SCLC initiation, we developed a novel airway organoid model that, for the first time, supports the culture of human airway cells alongside PNECs. Multicellular complexity of the organoids was characterised by scRNA-seq. Additionally, we established protocols for genetically engineering organoids with SCLC driver mutations and for quantitative imaging of the PNEC population.

Results: Our methods provide a versatile platform to monitor wildtype and mutant PNECs in response to various environmental cancer risk factors added to the organoid culture. We plan to screen for environmental carcinogens that induce malignant transformation of PNECs within these organoids.

Conclusions: On balance, our goal is to establish the first human model of lung neuroendocrine cancer initiation that integrates both genetic and environmental drivers. The models and experimental protocols we generate will offer a valuable toolkit for elucidating the mechanisms underlying the pathogenesis of lung neuroendocrine cancers and will help identify novel strategies for early detection and treatment

PT1.03.01 Precision Medicine Platform to Guide the Treatment of NSCLC

S.D. Merajver[1], A. Udager[1], A. Qin[1], K. Lagisetty[1], L. Bao[1], X. Cheng[1], H. Madhi[1], A. Banerjee[1], M.S. Jahromi[1], L. Goo[1], V. Kathawate[1], B. Vandenburg[1], M. Horn[1], D. Nancarrow[1], T. Rastogi[1], A. Liu[1], N. Gu[1], Z. Qin[1], H. Serhan[1], M. Aikins[1], V. Navani[2], J. Jefferies[3], M.S. Ali[4], M. Monument[2], J. Kratz[5], A. Smith[6], A. Chang[1], G. Kalemkerian[1], S. Fry[1], P. Ulintz[1], S. Nagrath[1], P. Hsu[1], M. Soellner[1], N. Merrill[1]
[1]University of Michigan, Ann Arbor/MI/USA ,[2]Tom Baker Cancer Centre, Calgary/AB/CA ,[3]University of Tennessee Health Science Center, Memphis/TN/USA ,[4]Weill Cornell Medicine, New York/NY/USA ,[5]University of California San Francisco, San Fracisco/CA/USA ,[6]The Rare Cancer Center Foundation, Durham/NC/USA

Introduction: Lung cancer (LC) remains the top cause of cancer-associated mortality worldwide, with a 10-year overall survival rate of only 5%. While most LCs are smoking related, 25% of non-small cell LC (NSCLC) are diagnosed in patients with little or no smoking history. Fusions involving anaplastic lymphoma kinase (ALK) are the oncogenic driver in ~3-7% of NSCLC. While inhibitors targeting the kinase domain of ALK have proven effective, inevitably, resistance develops with limited subsequent efficacious options. We aimed to integrate multiomic characterization and drug sensitivity testing of minimally cultured NSCLC samples to provide a ranked list of most effective drugs for each patient.

Methods: We developed a precision medicine platform (PMP) to screen patient-derived material (PDM) directly from the operating room with curated panels of drugs. PDM collected during clinically indicated procedures is plated in 3D-culture to generate patient-derived organoids (PDOs). PDOs are screened at therapeutically relevant doses, drawing from pharmacokinetic data for each drug. We have optimized an assay to rapidly screen for EML4-ALK fusions and can perform next-generation sequencing in ~7 days to integrate with drug screening results.

Results: To date, we have screened and molecularly characterized 77 NSCLC PDOs. Our cohort prioritized collection of EML4-ALK LC, resulting in 14 distinct ALK+ cases, with 13 patients having progressed on 2+ lines of therapy. While our dataset is enriched in non-smokers (32/80 screened models), we observed only 4 cases of LC with mutations in EGFR. Twelve models have mutations in KRAS, ¼ of those occurring in never-smokers. We demonstrate high quality drug screening data from low input samples (biopsies). In one case of EML4-ALK NSCLC, we collected PDM from two distinct anatomic spaces (pleural effusion and peritoneal fluid) and the screens yielded nearly identical results, highlighting the consistency of our assay. Our results recapitulate known resistance in samples previously exposed to therapy, demonstrating a strong negative predictive value. Sequencing identified diverse driver mutations in populations of both smokers and non-smokers.

Conclusions: Our PMP captures robust results that are consistent with known clinical pathogenesis. Prioritization of drug screening using compounds with diverse targets is critical when driver mutations are unknown to ensure we screened the most clinically relevant drugs for each tumor. We are currently collecting longitudinal data from enrolled patients in parallel with clinical trials to demonstrate the positive predictive value of our PMP. We additionally strive to demonstrate reproducibility to obtain Clinical Laboratory Improvement Amendments approval.

PT1.03.02 Single-Cell Profiling of Tumor Lineage Plasticity and the Immune Microenvironment in Transformed Small Cell Lung Cancer

J. Huang[1,2], Z. Zhang[3], G. Cai[3], W. Huang[4], J-J. Yang[1], J. Wang[3]
[1]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital, Guangzhou/CN ,[2]Guangdong Provincial People's Hospital Ganzhou Hospital, Ganzhou/CN ,[3]Sun Yat-sen University, Guangzhou/CN ,[4]Guangdong Provincial People's Hospital, Guangzhou/CN

Introduction: The transformation of non-small cell lung cancer (NSCLC) into small cell lung cancer (SCLC) is a recognized resistance mechanism of target-therapy, most often arising from EGFR-mutant lung adenocarcinoma (LUAD). However, the underlying molecular mechanisms of transformation remain poorly understood.

Methods: Single-cell RNA sequencing was employed to analyze the tumor cell heterogeneity and to map the intratumoral immune cell landscape of 73,195 cells from five LUAD, three transformed small cell lung cancer (T-SCLC) and four SCLC patients. Multiplex immunofluorescence (mIF) staining and in vitro studies were conducted to validate the stem-like feature of a malignant cell cluster and the enrichment and the function of interferon-stimulated gene-positive (ISG+) lymphocytes in transformation. Moreover, western blotting analyses further performed to detect the expression of neuroendocrine markers in LUAD cells after co-culture with MX1OE T cells, representing ISG+T cells,.

Results: Although increase intratumoral heterogeneity was observed upon SCLC transformation, a stem-like malignant cell subpopulation was identified to recur across subtypes and groups as the pioneering force of lineage plasticity for SCLC transformation. Further mIF staining and transcription factor analyses validated the stem-like feature of this cell cluster. Additionally, ISG+ T cells and B cells were enriched in T-SCLC, and further cell co-culture experiments disclosed that ISG+ lymphocytes promote neuroendocrine phenotypic shift in LUAD cells via type I interferons (IFN-Is). Deciphering cell-cell interactions revealed that the stem-like malignant cells could activated and attract ISG+ T cells. Finally, we developed an ISG-associated gene signature that significantly correlates with poor prognosis in LUAD patients.

Conclusions: Our findings provide a comprehensive understanding of the lineage plasticity and the immune landscape in T-SCLC, highlighting the crucial role of the stem-like cell cluster and ISG+ lymphocytes in LUAD-to-SCLC transformation.

PT1.03.03 Drug Repurposing for Metastatic Lung Adenocarcinoma Therapy Using AI-Guided Single-Cell Gene Expression Profiles

M.R.G. Fernandes[1], V.L. Schimidt Camargo[1], J. Souza[2], R. Aráujo[3], S. Santiloni Cury[4], R. P. Simões[4], P. Pintor dos Reis[3], R. Carvalho[1]
[1]Sao Paulo State University, UNESP, Brazil, Botucatu/BR ,[2]Health Technology Institute, SENAI CIMATEC, Salvador/BR ,[3]Faculty of Medicine, Sao Paulo State University (UNESP), Botucatu/BR ,[4]Sao Paulo State University (UNESP), Botucatu/BR

Introduction: Metastasis is the leading cause of cancer-related deaths, mainly due to therapeutic resistance. Drug repurposing offers a promising strategy for metastatic lung adenocarcinoma by identifying antineoplastic properties in existing drugs. Advances in single-cell RNA sequencing (scRNA-seq) enable high-resolution characterization of malignant cells, providing insights into transcriptional changes in metastasis. By integrating AI-driven network-based and machine-learning algorithms with scRNA-seq data, gene signatures of metastatic cells can be compared to drug-induced expression profiles, facilitating the identification of candidate drugs capable of reversing oncogenic programs. Despite the growing interest in this strategy, its application to metastatic lung adenocarcinoma remains limited. In this study, we applied scRNA-seq data and AI-based computational methods to identify candidate drugs capable of reversing gene expression signatures. By analyzing gene expression profiles from metastatic malignant cells in both smokers and never-smokers, we aimed to uncover novel therapeutic opportunities for drug repurposing.

Methods: We preprocessed and analyzed scRNA-seq data from 63 lung adenocarcinoma patients with brain and lymph node metastases, including samples from smokers and never-smokers, totaling 164,857 single cells from the Gene Expression Omnibus repository (GSE131907 and GSE123904) using Seurat v5.0.2. Differentially expressed genes between metastatic malignant and non-malignant cells were identified using the Seurat v5.0.2 FindMarkers function. Pathway enrichment analysis was performed with EnrichR, while drug prediction was conducted using the L1000FWD platform, which applies machine learning and network-based gene signature concordance analysis.

Results: Malignant cells were most abundant in brain metastases (39.7%), B lymphocytes in lymph node metastases (34.95%), and T lymphocytes dominated lung primary tumor (47%) and adjacent normal tissues in lung (30.02%) and lymph node (66.84%). Pathway enrichment analysis revealed key mechanisms driving tumor progression and metastatic adaptation. Common pathways across all sites included metabolic reprogramming, with a strong enrichment in glycolysis-related pathways, highlighting the tumor's dependence on this energy source. Kinase regulation and VEGFA-VEGFR2 signaling were also consistently enriched, reinforcing their roles in tumor progression and angiogenesis. Site-specific signatures were also detected: (i) primary lung tumors exhibited kinase activation; (ii) brain metastases displayed metabolic shifts characterized by mTOR signaling activation via fatty acid and glucose metabolism; and (iii) lymph node metastases showed activation of the p53 pathway and epithelial-mesenchymal transition (EMT), indicating increased plasticity and aggressiveness. Drug prediction analysis revealed both shared and site-specific pharmacological candidates, presenting new opportunities for drug repurposing. Cardiotonic glycosides were common across all tumor sites, while mTOR inhibitors and immunosuppressants were shared between metastatic and primary tumors. Corticosteroids and selective serotonin reuptake inhibitors (SSRIs) were specific to lymph node metastases, whereas histone deacetylase (HDAC) inhibitors and selective estrogen receptor modulators (SERMs) were unique to primary lung tumors.

Conclusions: These findings offer important insights into the molecular landscape of metastatic lung adenocarcinoma, revealing key pathways driving tumor progression. We identified promising therapeutic candidates, including site-specific drugs, by integrating pathway enrichment and drug repurposing analyses. Future "in vitro" assays using cell culture models will be conducted to validate these drug candidates for repurposing.

Introduction: Preclinical cancer models are crucial for advancing knowledge, research, and treatments in thoracic oncology. No resource is currently available to access preclinical cancer models focusing specifically on the requirements of the thoracic oncology community. The Virtual International Knowledgebase for Thoracic Oncology Research (VIKTOR) is a digital platform addressing this critical unmet need. VIKTOR's goal is to center the information from curated cancer model knowledge bases and single institutes toward the questions, priorities and needs of the researcher in thoracic oncology. VIKTOR will facilitate and accelerate research and collaborations among scientists, clinicians, and industry partners, fostering participation in identifying research priorities for the thoracic oncology community and the benefit of our patients.

Methods: Semantic search is used to retrieve information from open accessible and curated knowledge bases. Currently, data from Cellosaurus, PharmacoDB and UniProt/neXtProt are converted into RDF statements and stored in a triple store enabling SPARQL-based queries. Queries submission and retrieval of results in CSV files format are supported by a web interface. Knowledge from single institutes of the community will be integrated. VIKTOR supports the active participation of the scientists in prioritizing the research questions.

Results: VIKTOR is a searchable digital platform that permits to identify and retrieve information on preclinical cancer models tailored to the needs of researchers in thoracic oncology. Specific research questions can be addressed such as: "which lung cancer cell lines harbor ROS1 fusion genes?", "which cell lines have been modified to express a mutated gene X of interest?" or "which lung cancer cell lines have undergone sensitivity screenings for drug Y ". A list of available cell lines from open-access knowledge bases is then reported linked to relevant biological data such as omics profiles or drug sensitivity results. The reports are user-friendly and will incorporate a scoring system to help researchers selecting the most suitable preclinical models.

Conclusions: VIKTOR is an ongoing project of the Basic and Translational Science Committee (BaTS) of IASLC that supports researchers in accessing and querying data about preclinical cancer model systems. It retrieves data from open access resources and will integrate knowledge from single institutes of the community. The platform is centered toward the research priorities identified by the IASLC thoracic oncology community in order to facilitate rapid dissemination of information and collaboration. Presented on behalf of the Basic and Translational Science Committee of the IASLC

PT1.03.05 An Ai-Based Predictive Tool for Druggable Mutations in Lung Cancer Using Nationwide Comprehensive Genomic Profiling Data

H. Ikushima, K. Watanabe, A. Shinozaki-Ushiku, K. Oda, H. Kage
The University of Tokyo Hospital, Tokyo/JP

Introduction: Comprehensive genomic profiling (CGP) plays a pivotal role in precision medicine. However, the low probability of discovering mutation-based treatments, despite the financial and time burden, may prevent eligible patients from undergoing CGP. To enhance the efficiency and efficacy of cancer precision medicine, it is critical to identify patients who are likely to benefit from CGP. This study aims to identify patient characteristics associated with the discovery of mutation-based treatments through CGP and to develop an intuitive AI tool to predict the probability of identifying druggable mutations.

Methods: To train a predictive AI model, we used clinical data from 3,470 lung cancer patients (Cohort 1) who underwent CGP between Jun 2019 and Nov 2023 and were registered in the Center for Cancer Genomics and Advanced Therapeutics (C-CAT) database, which covers 99.7% of CGP performed in Japan. Using clinical information available prior to CGP, we developed an eXtreme Gradient Boosting (XGBoost) model to predict the detection of druggable mutations. SHapley Additive exPlanations (SHAP) was employed to extract features that contribute to the model prediction. Using the identified clinical factors as input, another AI model was built and deployed as a smartphone and web-based application to predict the probability of identifying druggable mutations. The app's performance was tested on clinical data from 1,307 lung cancer patients (Cohort 2) who underwent CGP between Dec 2023 and Nov 2024.

Results: The predictive AI model trained on Cohort 1 achieved an AUROC of 0.85 (95% confidence interval [CI]: 0.82-0.89, sensitivity: 0.82, specificity: 0.73). A separate model, excluding patients with at least one druggable mutation detected by small companion diagnostic tests before CGP, showed an AUROC of 0.79 (0.74-0.84). Positive SHAP values were associated with adenocarcinoma and the number of metastatic sites, while negative SHAP values were with male sex and smoking history. These relationships were consistent across tissue and liquid CGP cases. Notably, among tissue CGP cases, patients with bone or lung metastases exhibited a significantly higher rate of druggable mutation detection compared to those without (bone: $p = 0.011$; lung: $p < 0.001$). A streamlined AI model was retrained using the most influential clinical factors and deployed as a smartphone and web-based application. When tested on Cohort 2, the app demonstrated predictive accuracy with an AUROC of 0.77 (0.74-0.79) and a Brier score of 0.19.

Conclusions: We developed an AI model that predicts the probability of identifying druggable mutations by using pre-CGP clinical data. We also identified key clinical factors predictive of druggable mutation detection in lung cancer through explainable AI analysis of nationwide CGP data. Based on these findings, an easy-to-use smartphone and web-based application was developed to predict the probability of identifying druggable mutations. This model could expand access to targeted therapies by facilitating broader utilization of CGP tests.

Introduction: Amivantamab, an EGFR-MET bispecific antibody, plus lazertinib, a third-generation EGFR tyrosine kinase inhibitor (TKI), is approved for first-line treatment of EGFR-mutated advanced NSCLC. In the protocol-specified final overall survival (OS) analysis (median follow-up, 37.8 months), amivantamab-lazertinib demonstrated a statistically significant and clinically meaningful improvement in OS versus osimertinib (HR, 0.75; P<0.005), with the median OS benefit projected to exceed 1 year (Yang ELCC 2025). One key rationale for combining amivantamab with lazertinib was to proactively address acquired resistance mechanisms to third-generation TKIs. An early analysis showed that first-line amivantamab-lazertinib significantly reduced acquired EGFR-based and MET-based alterations (P<0.05 versus osimertinib), without significant increases in other known pathways (Besse ESMO 2024). Here we report updated acquired resistance mechanism data.

Methods: Participants with previously untreated EGFR-mutated (Ex19del/L858R) advanced NSCLC were randomized 1:1 to receive amivantamab-lazertinib (n=429) or osimertinib (n=429). Next-generation sequencing (Guardant 360 CDx) was used to analyze detectable circulating tumor DNA in paired blood samples collected at baseline and end of treatment (EOT; defined as at disease progression or at/within 90 days of treatment discontinuation). Mutational heterogeneity was quantified using the Shannon Diversity Index (Oh et al. Sci Reports 2019;9:4542). All P-values are nominal.

Results: Among participants who discontinued treatment and had baseline ctDNA data, 148/187 (79%) in the amivantamab-lazertinib arm and 198/218 (91%) in the osimertinib arm had matched EOT ctDNA data. MET amplification was significantly reduced in participants receiving amivantamab-lazertinib versus osimertinib (3.4% vs 13.1%; P=0.002). Further, MET amplifications were enriched among osimertinib-treated participants who experienced early disease progression (≤6 months post-randomization); there were too few MET amplifications to draw conclusions for amivantamab-lazertinib. Secondary EGFR mutations (eg, C797S) were also significantly lower in the amivantamab-lazertinib versus osimertinib arm (1.4% vs 7.6%; P=0.01). The 2 participants in the amivantamab-lazertinib arm with acquired EGFR mutations only received amivantamab for one cycle and continued on lazertinib. Differences between arms for other known resistance pathways were not significant (Figure).

Compared to amivantamab-lazertinib, mutational heterogeneity was significantly increased after osimertinib treatment (P<0.05); this difference was most pronounced among participants with acquired EGFR- and MET-based alterations. Additional details, including data on outcomes, will be presented at the meeting.

Conclusions: In this updated analysis, significantly lower rates of EGFR and MET resistance alterations were seen in the amivantamab-lazertinib arm vs osimertinib. These findings further suggest that amivantamab-lazertinib, with its statistically significant and clinically meaningful survival benefit over osimertinib, is changing the underlying biology of EGFR-mutant disease.

PT1.04.01 Incidental Pulmonary Nodule Programs (IPN) Working Together With LDCT Scans and Artificial Intelligence (AI) Increase Lung Cancer Detection

L.E. Raez [1], B. Gotkin[2], A. Searle[2], M. Feinberg[1], O. McEachin[1], J. Goldman[2], M. Fernandez-Gomez[1], M. Block[1]
[1]Memorial Cancer Institute/Florida Atlantic University, doral/FL/USA ,[2]Memorial Healthcare System, Pembroke Pines/FL/USA

Introduction: Low-Dose CT (LDCT) scan is considered standard for lung cancer screening (LCS) in high-risk populations, but significant barriers remain, and screening rates are low. Social determinants of health create barriers to screen underserved populations and current eligibility criteria do not include never-smokers and younger populations. Incidental Pulmonary Nodule Programs (IPN) programs use artificial intelligence (AI) driven tools to identify patients who have pulmonary nodules detected on imaging studies done for other reasons. These tools facilitate identification, classification, and management of pulmonary nodules. Preliminary comparisons like the DELUGE trial in Mississippi have shown that IPN programs can detect more lung cancers than traditional LDCT programs.

Methods: We created an IPN program at Memorial Cancer Institute/Memorial Healthcare System in Broward, Florida to complement our LDCT program. The goal was to identify lung cancers in individuals with limited access to or not covered by screening and thus eliminate disparities. Large healthcare systems like us perform thousands of CT scans every month, making manual review of results impossible for nodule identification. To address this challenge, we used an AI solution called ILUMINATE to interact with our electronic medical records (EMR) EPIC system to detect and triage lung nodules (high, intermediate or low risk). The system reviewed results from all CT scans that included portions or the lung, such as CT chest, abdomen, spine, and calcium score scans from all five of our hospitals. A nurse navigator managed the program, reviewing reports from the AI system and presenting cases to a weekly lung nodule review group that included pulmonologists and thoracic surgeons. Each case was recommended either for workup (e.g. short interval CT, PET scan, biopsy, surgery), or continued follow-up in the LCS program. Here we compare results from the first 20 months of the IPN program with results from same period of the LDCT program.

Results: From May 2023 to January 2025 2,423 individuals were screened in the LDCT group of which 781 (33%) had follow-up scans. A slight majority (51%; 1,246) were female and non-Hispanic whites (NHW) were 1453 (60%). Median age was 71y (25-99y). Ten patients (0.4%) were diagnosed with lung cancer. In the IPN program 205,022 radiology reports were screened by the AI and 6,685 individuals were identified for follow up. Most were female (58%; 3,877) and NHW 4010 (60%). Median age was 70y (20-100y). From this IPN group 817 patients (17%) were enrolled in the LCS program for follow up and 127 (1.9%) were diagnosed with lung cancer. Most of the patients in the LDCT group and IPN group were diagnosed with early stage (I/II) NSCLC

Conclusions: Our IPN program significantly improves lung cancer detection, detecting more lung cancers than the LDCT program over the same period. There were no significant differences in age, gender or race between these two groups. AI tools made it possible to review the large number of studies generated in a health care system, leveraging limited human resources to address a large unmet need. Longer follow up will allow us to present survival data.

PT1.04.02 Performance of Lung Nodule and Cancer Risk Calculators in Identifying Primary Lung Cancer Across Screening and Incidental Nodule Populations

F.A.C. Sarmento Neto, F.M.d. Gouvêa, L. Pontual Lima, P.A. Sarmento, I.V. Secundo, T.N. Béder, J.F.d.P. Moura, C.F.J.d.S. Menezes, H.V.S.d. Fonseca, F.G.N.d. Silva, J.E. Freire da Fonte, L. Casali, D.V. Ferraz de Carvalho, L.d.F. Souto, M. Tavares de Morais, J.P.B. Pereira, R.L. Alencar
Real Hospital Português de Beneficência em Pernambuco, Recife/BR

Introduction: Pulmonary risk calculators support decision-making in nodule management. Nodule-based models use imaging characteristics, while lung cancer risk models rely on demographic-clinical data. This study compared the performance of these tools in distinguishing confirmed primary lung cancer from non-investigated nodules in a combined screening and incidental cohort, with subgroup analyses by tobacco exposure.

Methods:

We retrospectively analyzed 290 individuals evaluated between 2023 and 2024 in a multidisciplinary program. A total of 74 cases of primary lung cancer were histologically confirmed. Five nodule-based calculators - Brock University cancer prediction equation (Brock Model), Mayo Clinic Model, Herder Model, Veterans Affairs (VA) Model, and Cleveland Model and three lung cancer risk models: Liverpool Lung Project risk (LLP) Model, PLCOm2012, Simplified PLCOm2012. Risk scores were compared between cancer cases and nodules without histologic investigation using Mann-Whitney U tests. Subgroup analyses included individuals with incidental nodules (n=195) and those without a history of tobacco exposure (n=116). Significance was set at $p<0.05$.

Results: In the overall cohort, four nodule-based calculators (Brock Model, Mayo Clinic Model, Herder Model, VA) significantly differentiated cancer cases from nodules without diagnosis ($p<0.05$ for all). The VA Model demonstrated the highest discrimination (mean 86.3 vs. 43.1, $p<0.001$). The Cleveland model showed no significant difference ($p=0.850$). Lung cancer risk models—Liverpool, PLCOm2012, and Simplified PLCOm2012—did not distinguish between groups ($p>0.19$ for all).In the incidental subgroup, the VA model again had the best performance (86.8 vs. 37.8, $p<0.001$). Brock Model (27.2 vs. 13.1, $p<0.001$), Mayo Clinic Model (41.1 vs. 15.9, $p=0.012$), and Herder Model (63.1 vs. 45.8, $p=0.015$) were also significant. Cleveland Model was not ($p=0.490$). Among cancer risk models, only LLP Model was statistically significant (2.66 vs. 1.24, $p=0.025$); Simplified PLCOm2012 showed a trend ($p=0.094$).In individuals without tobacco exposure, the VA model was the only significant tool ($p<0.001$), indicating robustness beyond smoking-related populations. Brock model showed a non-significant trend ($p=0.130$), while Mayo Clinic Model, Herder Model, Cleveland Model, and all cancer risk models lacked discriminatory capacity.

Conclusions: Nodule-based calculators, especially the VA model, outperformed lung cancer risk models in identifying primary lung cancer. The VA model consistently demonstrated robust performance across all subgroups, including individuals without tobacco exposure. Notably, the LLP Model was the only lung cancer risk calculator to show discriminatory capacity in individuals with incidental nodules. These findings support the integration of imaging-based models, particularly VA Model, alongside selective use of clinical-demographic tools like LLP Model, in multidisciplinary pulmonary nodule programs.

PT1.04.03 The LEAP Study: A Biospecimen Bank for Validation of Liquid Biomarkers in a Lung Cancer Screening Cohort

E. Ostrin[1], J. Dennison[2], S. Gendarme[3], N. Kettner[2], J. Erasmus[2], M. Godoy[2], J. Philley[4], M. Antonoff[2], M. Adams[2], A. Grainger[5], J.C. Tucker[6], D. Shersher[7], B. Putnam[8], C. Lee[9], R. Ryu[10], A. Fan[11], C. Chouaid[3], B. Maitre[3], N. Carballo[12], S. Hanash[2]
[1]UT MD Anderson Cancer Center, Houston/TX/USA ,[2]The University of Texas M. D. Anderson Cancer Center, Houston/TX/USA ,[3]Université Paris-Est-Créteil, Créteil/FR ,[4]The University of Texas Health Science Center, Tyler, Tyler/TX/USA ,[5]OhioHealth, Columbus/OH/USA ,[6]DCH Health System, Tuscaloosa/AL/USA ,[7]Cooper University Health Center, Camden/NJ/USA ,[8]Baptist MD Anderson Cancer Center, Jacksonville/FL/USA ,[9]Cedars-Sinai, Los Angeles/CA/USA ,[10]University of Colorado Anschutz School of Medicine, Aurora/CO/USA ,[11]Stanford Health Care, Palo Alto/CA/USA ,[12]MD Anderson Cancer Center Madrid, Madrid/ES

Introduction: Liquid biomarkers could improve the effectiveness of lung cancer screening (LCS) by low-dose computed tomography (LDCT) through more accurate lung cancer (LC) risk stratification and nodule malignancy risk assessment. The LEAP study aims to establish a reference set to validate the most promising cancer biomarkers in the context of LCS.

Methods: This study is a prospective international cohort (USA, France, Spain) enrolling active or former smokers at high LC risk based on National Comprehensive Cancer Network Guidelines (v1.2014) into an LCS program. Participants underwent three annual rounds of LDCT-LCS with blood specimens collected at each screening timepoint. Questionnaires and medical chart reviews were utilized to determine who was later diagnosed with lung and/or other cancers.

Results: Between 2014 and 2019, 2,846 participants enrolled who underwent LDCT: 2,842 at baseline, 2,097 at year 1 (73%) and 1,779 at year 2 (62%). The rates at baseline, year 1, and year 2 were as follows: positive scans (13%, 7.5%, 7.5%), false-positive (12%, 6.6%, 6.9%) and screen-detected LC (1.1%, 0.8%, 0.7%). After 5 years of follow-up, 72 LC were detected: 56% stage I, 13% stage II, 17% stage III and 14% stage IV. The LEAP biobank collected 6,188 blood specimens, including 126 pre-diagnostic for LC (within 5 years before diagnosis) and 201 pre-diagnostic for other cancers.

Conclusions: The LEAP cohort is a valuable longitudinal database of subject data, LDCT imaging, and matched blood specimens for biomarker validation, aiming to address unmet clinical needs in the context of LCS.

PT1.04.04 Biomarker-Based Eligibility for Lung Cancer Screening - Validation of Protein-Based INTEGRAL-Risk Model in the LC3 Consortium

M. Johansson[1], H. Zahed[1], X. Feng[1], M. Johansson[2], C. Amos[3], R. Hung[4], D. Muller[5], H.A. Robbins[1], (. Lung Cancer Cohort Consortium[6]
[1]International Agency for Research on Cancer (IARC), Lyon/FR ,[2]Umeå Universitet, Umeå/SE ,[3]The University of New Mexico Comprehensive Cancer Center, Albuquerque/NM/USA ,[4]Lunenfeld-Tanenbaum Research Institute, Toronto/ON/CA ,[5]Imperial College, London/GB ,[6]Multiinstitutional, Lyon/FR

Introduction: Current eligibility criteria for lung cancer screening by LDCT exclude approximately 50% of lung cancer cases whilst including many individuals at low risk who may not benefit from screening. Biomarkers have the potential to enhance smoking-based risk assessment tools. We previously developed a fit-for-purpose protein biomarker panel (INTEGRAL panel) comprising 21 proteins selected to inform lung cancer screening. We aimed to develop a biomarker-based risk model for use in LDCT-screening using a robust study design in the target population.

Methods: The Lung Cancer Cohort Consortium (LC3) involves 25 population cohorts from around the world with pre-diagnostic blood and risk factor information on up to 3,000,000 study participants, including 70,000 incident lung cancer cases. We designed 14 independent case-cohorts in LC3, including 2,305 randomly sampled sub-cohort participants and 1,390 incident lung cancer cases. All participants had a history of smoking, and cases were diagnosed within three years of blood collection. We developed the protein-based INTEGRAL-Risk model using data from seven case-cohorts, incorporating age, smoking history, and absolute concentrations of 13 proteins. Model testing was performed in seven independent cohorts by assessing model calibration and discrimination and comparing performance with existing risk assessment tools.

Results: In the testing set (1,161 sub-cohort participants and 583 lung cancer cases), the INTEGRAL-Risk model demonstrated superior discrimination for lung cancer incidence over one year compared to the smoking-based PLCOm2012 model (AUC: 0.88 [95% CI: 0.85-0.90] vs. 0.79 [95% CI: 0.75-0.83]; p<0.001). The model was well-calibrated for one-year lung cancer risk prediction (expected/observed ratio: 0.86 [95% CI: 0.61-1.25]). The USPSTF screening criteria identified 25% of individuals with smoking exposure as eligible for LDCT screening, capturing 63% of lung cancer cases within one year. Using a risk threshold that selected an equivalent 25% of participants, the INTEGRAL-Risk model identified 85% of lung cancers as eligible for screening (Figure 1). Stratified analyses by race/ethnicity demonstrated consistent model performance across white (AUC: 0.88 [95% CI: 0.84-0.92]), black (AUC: 0.90 [95% CI: 0.81-0.97]), and Asian (AUC: 0.88 [95% CI: 0.82-0.93]) participants.

Conclusions: This study represents a major effort from an international consortium to develop a biomarker-based risk prediction tool for use in LDCT screening. The protein-based INTEGRAL-Risk model improves upon existing risk assessment tools for identifying high-risk individuals with a history of smoking. These findings underscore the potential of biomarker-based risk models to enhance LDCT screening efficiency by better targeting individuals likely to benefit.

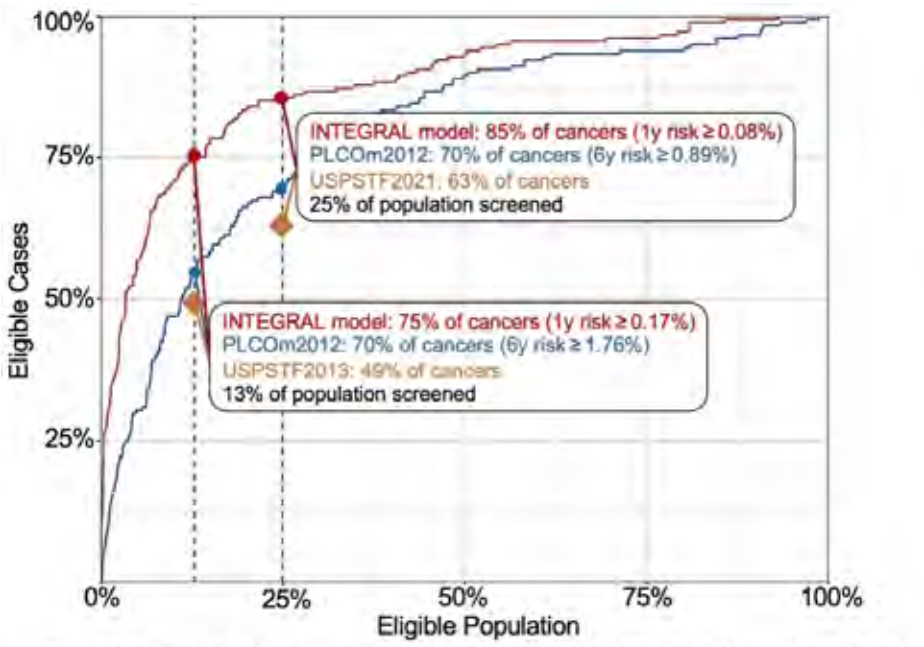

Figure 1. *Overview of the study design (a) cohorts participating in the INTEGRAL study of risk biomarkers (b). Cohorts marked in grey were included in the discovery phase to design the INTEGRAL protein panel. Cohorts marked in purple were used to train the protein-based INTEGRAL-Risk model, and cohorts marked in green were used to test the INTEGRAL-Risk model*

PT1.04.05 Subclassification of Abnormal Cells Into Precancerous and Malignant Categories Based on 3D Cellular Imaging

M.G. Meyer[1], D. Wilbur[2], A. Nelson[1]
[1]VisionGate, Inc., Woodinville/WA/USA ,[2]Harvard Medical School, Boston/MA/USA

Introduction: VisionGate's Cell-CTTM platform captures 3D images of cells in isometric, sub-micron resolution and measures >500 orientation-invariant 3D features in each cell. The LuCED® assay uses home-collected sputum to detect early-stage lung cancer through AI discovery of abnormal cells across the cytologic categories of atypia through to malignancy. Results show that early-stage lung cancer is detected with sensitivity and specificity both exceeding 90%, and the sensitivity to biopsy-confirmed stage 1 NSCLC was 93.8%. In this context, we hypothesize that the abnormal cell population may be sub-classified into malignant and pre-cancer categories. This application will broaden the clinical scope of the LuCED assay to prioritize patient triage in cases where frankly cancerous cells are detected. Cases without malignant cells would default to standard protocols of vigilance with a likelihood of pre-cancer.

Methods: Abnormal cells detected with LuCED were further classified into cancer and pre-cancer categories using an AI-supervised learning process involving cytologically defined cells in classes of pre-cancer (N=623) and malignancy (N=374). The Cell-CT measured 503 3D features for each cell and adaptively boosted logistic regression separated the two classes. Ten-fold cross-validation ensured that the resulting classifier was not overtrained.

Results: A model involving six features emerged from the training process, producing an area under the ROC of 0.81. A potential operating point produced these results: 70% detection of malignant cells, with 30% of malignant cells called pre-cancer; 80% detection of pre-cancer cells, with 20% of pre-cancer cells called malignant; None of the abnormal cells were called normal.

Conclusions: These results demonstrate the efficacy of 3D cell analysis in characterizing subtle aspects of abnormal cell morphology to assess whether a malignant process is likely to be present. This new AI classifier may find application in the COPD patient population and in improving the management of IPNs. In such populations, a clear indication of malignancy is urgently needed to initiate curative/lifesaving therapy, particularly in early-stage disease, where such treatments will be most effective.

PT1.05.01 Impact of Endobronchial Ultrasound-Guided Intranodal Forceps Biopsy on Next-Generation Sequencing

K. Sato[1], Y. Matsumoto[1,2], H. Furuse[1], T. Tsuchida[1]
[1]National Cancer Center Hospital, Tokyo/JP ,[2]National Cancer Center Hospital, Tokyo /JP

Introduction: Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) offers high diagnostic accuracy and provides specimens well-suited for next-generation sequencing (NGS). The success rate of NGS has been reported to correlate with the number of punctures and core tissues obtained. However, since obtaining sufficient samples from tumors in TBNA is sometimes difficult, we have actively incorporated standard-sized intranodal forceps biopsy (IFB) as an adjunct. The advantage of IFB over TBNA is that it allows the collection of tissue specimens rather than cytological specimens, and using standard-sized forceps enables the collection of larger, higher-quality specimens than conventional mini-forceps. In this study, we aimed to evaluate the impact of adding IFB to TBNA on NGS.

Methods: We retrospectively collected consecutive patients diagnosed with non-small cell lung cancer (NSCLC) via EBUS-TBNA from metastatic hilar/mediastinal lymph nodes (LNs) at our institution between April 2020 and March 2024. Of them, cases submitted to the amplicon-based NGS targeting 46 gene aberrations using those specimens were extracted. Cases in which a sufficient number of core tissues could be obtained by TBNA (i.e., 5 or more) were excluded. The remaining cases were divided into those with IFB (combined group) and those without (TBNA group), and the results of the NGS were compared between the two groups. NGS was defined as successfully analyzed if any driver oncogene or a negative result for all actionable genetic alterations (i.e., EGFR, ALK, ROS1, BRAF, RET, MET, KRAS, and HER2) with approved drugs was detected.

Results: Of the total 1,414 EBUS-TBNA procedures, 1,163 targeted LNs of NSCLC and NGS were submitted in 436. Ultimately, 325 patients met the selection criteria, with 275 (84.6%) in the combined group and 50 (15.4%) in the TBNA group. The median age was 69 years (range 25-89), 215 patients (66.2%) were male, and 208 (64.0%) had adenocarcinoma. The median short axis size of the LNs was 14.2 mm (range, 3.8-46.3), and 253 (77.8%) targeted mediastinal LNs. The TBNA group had more male patients and cases in stages I to III, but the other factors were comparable between the two groups. The overall NGS success rate was 86.2%, and the most common gene aberration was EGFR in 58 (17.8%), followed by KRAS in 35 (10.8%), ALK in 18 (5.5%), and others in 58 (17.8%) at various frequencies. Univariable analysis demonstrated that the combined group showed a significantly higher NGS success rate than the TBNA group (88.0% vs. 76.0%, p = 0.042). Multivariable analysis revealed that only the combined group was significantly associated with a higher NGS success rate (adjusted odds ratio 2.35; 95% confidence interval 1.06-4.99; p = 0.035).

Conclusions: Our results suggest that IFB complements the success of NGS when added to TBNA. IFB is a valuable alternative if TBNA cannot obtain sufficient samples.

PT1.05.02 Development of an AI Image Analysis System for Malignancy Classification in Rapid On-Site Cytologic Evaluation of Lung Cancer

T. Sakai[1], K. Kirita[2], M. Takahashi[1], Y. Matsumoto[3], R. Hirama[4], N. Awano[5], Y. Tanaka[1], H. Izumi[1], H. Udagawa[1], E. Sugiyama[1], S. Umemura[1], Y. Zenke[1], S. Matsumoto[1], K. Yoh[1], K. Goto[1]
[1]National Cancer Center Hospital East, Kashiwa/JP ,[2]Ageo Central General Hospital, Ageo/JP ,[3]National Cancer Center Hospital, Tokyo/JP ,[4]Chiba University, Chiba/JP ,[5]Japanese Red Cross Medical Center, Tokyo/JP

Introduction: Rapid on-site cytologic evaluation (ROSE) during endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) reduces the need for repeated puncture procedures and the complication rate of bronchoscopy. However, ROSE is not widely utilized due to limited human resources, particularly the availability of staff to classify malignant and benign cells. This study aims to develop an artificial intelligence (AI) image analysis system to classify individual cells observed in ROSE during EBUS-TBNA as malignant or benign.

Methods: Patients suspected of having lymph node metastasis from lung cancer who underwent EBUS-TBNA were prospectively enrolled at five hospitals in Japan. Pathological slides using the Diff-Quik staining method were obtained from each patient, and images were captured using a microscope with a 40x objective lens. Cytotechnologists classified the individual cells observed into five types of benign cells (endothelial cell, inflammatory endothelial cell, macrophage, lymph cell, white blood cell) and four types of malignant cells (small cell carcinoma, adenocarcinoma, squamous cell carcinoma, other non-small cell lung cancers). A deep learning AI image analysis system was developed, and its performance was evaluated. This study was conducted in collaboration with NEC.

Results: Between August 2023 and September 2024, 128 patients were enrolled in this study. Of these, 108 cases were analyzed after excluding those with low-quality specimen images or without prepared pathology slides. The final diagnoses of the punctured lymph nodes included adenocarcinoma in 38 cases, squamous cell carcinoma in 13 cases, non-small cell lung cancer not otherwise specified in 18 cases, small cell carcinoma in 22 cases, and benign in 17 cases. Among them, 8184 cells were selected, with 2200 cells categorized as benign and 5984 cells categorized as malignant. The cases were divided into a training set (74 cases, 4763 cells), a validation set (15 cases, 1590 cells), and a test set (19 cases, 1831 cells). The training and validation sets were used for AI development, while the test set was used for performance evaluation. The AI's sensitivity for diagnosing malignancy in individual cells in the test set was 0.73 (95% confidence interval, 0.71-0.75), specificity was 0.97 (95% CI, 0.94-0.98), and positive predictive value was 0.99 (95% CI, 0.98-0.99).

Conclusions: The AI developed in this study demonstrated high specificity in determining whether individual cells observed in ROSE of lung cancer are malignant or benign. This system could assist in diagnosis during ROSE, improving diagnostic efficiency.

PT1.05.03 Comparison Between Lymph Node Station- and Zone-Based Classification: Analysis With the 9th IASLC Node Descriptors in Surgically Resected NSCLC

S. Kim, J.K. Yun, G.D. Lee, S. Choi, H.R. Kim, Y-H. Kim, D.K. Kim, S-I. Park
Asan Medical Center, Seoul/KR

Introduction: The International Association for the Study of Lung Cancer (IASLC) has introduced a 9th staging, dividing pN2 into pN2a and pN2b. We adopted the newly subdivided N descriptors to reclassify based on the involved lymph node (LN) zones or LN stations and then compared the discriminative abilities of these classifications.

Methods: A retrospective analysis was conducted on patients who underwent complete resection with systematic LN dissection for non-small cell lung cancer (NSCLC) diagnosed as pathological stages I-III, between 2005 and 2022. The N classification was divided into four categories according to 9th TNM staging: N0, N1, N2a, and N2b. LN zones were defined by grouping the LN stations: peripheral or hilar for N1 nodes, and upper mediastinal, lower mediastinal, aortopulmonary, and subcarinal for N2 nodes. The concordance index (C-index), Akaike Information Criterion (AIC), and R2 were calculated to assess the discriminatory power of the two classification systems.

Results: A total of 11,047 patients (6112 male; median age: 62.9 years) were analyzed. The median follow-up was 57.0 months. Multivariable analysis revealed that the subdivided N descriptors, based on both lymph node stations and zones, independently predicted overall survival(OS) and freedom from recurrence (FFR). When classified using the zone-based method, the N2a and N2b groups exhibited lower 5-year survival rates and higher hazard ratios (HRs). The zone-based classification demonstrated a discrimination ability comparable to that of the station-based classification as evidenced by a similar C-index (0.7679 vs. 0.7679), lower AIC (43,235 vs. 43,241), and higher R2 (0.167 vs. 0.166) values.

Conclusions: The discrimination ability was not significantly different between station-based and zone-based N descriptors. The new concept of N classifications could be considered for future revisions of N descriptor for Lung cancer.

PT1.05.04 Use of an Ultrathin Bronchoscope With a Larger Working Channel Enhances Diagnostic Yield in Cone-Beam CT-Guided Transbronchial Biopsy

N. Kawakita, A. Baba, S. Matsui, E. Takehara, K. Fujimoto, T. Takeuchi, N. Miyamoto, A. Morishita, H. Toba, H. Takizawa
The University of Tokushima Graduate School, Tokushima/JP

Introduction: Cone-beam computed tomography (CBCT)-guided transbronchial biopsy (TBB) using an ultrathin bronchoscopy (UTB) may be useful for diagnosing peripheral lung lesions. Commercially available UTBs have working channel diameters of 1.2 mm (small channel; SC-UTB) and 1.7 mm (large channel; LC-UTB). The latter can be used in combination with (radial endobronchial ultrasound (R-EBUS), which may be even more useful. This study aimed to compare the outcomes of SC-UTB and LC-UTB with R-EBUS in CBCT-guided TBB.

Methods: This study retrospectively included patients with pulmonary lesions ≤30 mm who underwent CBCT-guided TBB using UTB between October 2016 and November 2024. The UTB and biopsy forceps were advanced to the target bronchus under virtual bronchoscopic navigation and 2D-fluoroscopy. For cases using SC-UTB, CBCT was performed with forceps inserted. In cases using LC-UTB, CBCT was performed with forceps inserted after inserting the R-EBUS probe. We used inverse probability weighting to adjust for confounding variables and the outcomes were compared between SC-UTB group and LC-UTB with R-EBUS group.

Results: SC-UTB was used in 89 patients, and LC-UTB with R-EBUS in 76 patients. The inverse probability-weighted cohort represent 306 weighted patient cases (SC-UTB ,154; LC-UTB, 152). In the weighted cohort the diagnostic yield was 64.9% and 75.7% in cases using SC-UTB and LC-UTB with R-EBUS, respectively, showing a significantly higher diagnostic yield with the latter (p=0.040). The proportion of re-navigation after the primary CBCT decreased (47.4% vs. 26.1%; p<0.001) and reduced number of CBCT scans during examination (mean 1.8 times vs. 1.1 times; p<0.001)) in the LC-UTB with R-EBUS group.

Conclusions: In CBCT-guided TBB using UTB for peripheral pulmonary lesions, the use of LC-UTB allows the use of R-EBUS, which is expected to result in a higher diagnostic yield and a reduced number of CBCT scans compared with the use of SC-UTB.

PT1.06.01 ERBB2 (HER2) Fusions in Lung Cancer Are Targetable by Anti-HER2 Small Molecules and Antibody-Drug Conjugates

M. Ladanyi
Memorial Sloan Kettering Cancer Center, New York/NY/USA

Introduction: ERBB2 (HER2) Fusions in Lung Cancer are Targetable by Anti-HER2 Small Molecules and Antibody-Drug Conjugates Juan Luis Gomez Marti1,2, Tom Zhang1,3, Rohan Masters1,3 , Ryan Cheng1,3, Marissa Mattar1, Leo Gili1, Christopher A Febres-Aldana1,2, Romel Somwar1,2 and Marc Ladanyi1,2 Affiliations:1 Department of Pathology and Laboratory Medicine, Memorial Sloan Kettering CancerCenter, New York, NY, 10065, USA2 Human Oncology and Pathogenesis Program, Memorial Sloan Kettering Cancer Center, New York, NY, 100653 Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, NY, 10065 Background: ERBB2 amplification and ERBB2 activating mutations are predictive biomarkers for targeted therapies including the antibody-drug conjugate trastuzumab deruxtecan (T-DXd) and small molecule kinase inhibitors such as tucatinib. However, gene rearrangements involving ERBB2 remain understudied, especially in lung cancers. Here we performed a comprehensive pan-cancer analysis of the landscape of ERBB2 fusions and performed functional in vitro studies of a representative ERBB2 fusion.

Methods: A large institutional tumor cohort, prospectively profiled using MSK-IMPACT (genomic DNA) and MSK Solid Fusion (RNA) next-generation sequencing platforms, was interrogated for ERBB2 fusions. All structural variants (SV) involving ERBB2 were reviewed using Integrative Genome Viewer. Putative oncogenic ERBB2 fusions were defined as intergenic SVs preserving its tyrosine kinase domain (TKD, exons 18 to 24). Total or partial TKD truncation was considered as loss-of-function. Reading frame status, partner position in the chimeric transcript (5' or 3'), mechanism of SV formation (translocation or intrachromosomal rearrangement), and co-occurrence with ERBB2 amplification were annotated. Oncogenicity was assessed by interleukin 3-withdrawal assays in murine Ba/F3 cells or growth of transfected human bronchiolar epithelial (HBEC) cells in immunocompromised mice.

Results: Ninety-eight ERBB2 SV were detected amongst 87,266 profiled tumors (including 19,980 non-small cell lung cancers) with 33 (34%) retaining an intact TKD. Two fusion topologies were identified: 1) fusions involving upstream/5' partners fused to ERBB2 TKD (21/33, 64%) recapitulated the structure of known kinase fusions with the fusion partner contributing dimerization domains and/or aberrant high expression; 2) fusions of ERBB2 including TKD to downstream/3' partners (12/33, 36%) consistently replaced the C-terminal domain of ERBB2 (which contains its ubiquitination site at residue 1091) and recurrently involved signaling adapters as partners, e.g. ERBB2::GRB7 and ERBB2::SHC1. Both of these fusions retained the trastuzumab binding site and were associated with focal ERBB2 amplification/gains (22/33, 66%). The majority of ERBB2 fusions in the context of amplification were the result of intrachromosomal rearrangements (15/22, 68%) involving copies of the amplified ERBB2 allele fused to neighboring genes at 17q12 (IKZF3, STARD3, GRB7, TCAP). The ERBB2::SHC1 translocation involvingSHC1 at 1q21 (n=2, 0.01%) was the most common ERBB2 fusion in lung cancers lacking RTK/RAS/RAF canonical drivers, including ERBB2 amplification. Expression of ERBB2::SHC1 transformed Ba/F3 and HBEC cells. ERBB2::SHC1 was proficient at activating common growth and survival pathways in HBEC cells. Treatment of tumorigenic lung cells expressing ERBB2::SHC1 with afatinib, tucatinib, or T-DXd blocked cell growth and induced apoptosis.

Conclusions: ERBB2/HER2 fusions are rare oncogenic drivers in lung cancer. These tumors are candidates for therapy with FDA-approved HER2 antagonists. The subset of recurrent ERBB2 fusions with C-terminal/3' partners may represent an alternative mechanism of fusion oncogenicity.

PT1.06.02 Distinct Bronchoalveolar Lavage Fluid Microbiome and Metabolome Profiles in EGFR-Mutated and Wild-Type Non-Small Cell Lung Cancer

L. Wu, Z.J. Huang, P.P. Chen, W.C. Luo, Y.L. Peng, Z.H. Chen, C.R. Xu, Y. Deng, Y.Q. Le, G.H. Huang, J. Li, Q. Zhou
Guangdong Provincial People's Hospital, Guangzhou/CN

Introduction: Substantial differences exist in the tumor immune microenvironment between EGFR-mutated and wild-type lung cancer patients. Emerging researches indicates that bronchoalveolar lavage fluid (BALF) microbiota modulate lung local immune responses and contribute critically tumor initiation, progression and therapeutic outcomes. However, no studies to date have systematically characterized the BALF microbiota and metabolome profiles in NSCLC patients stratified by EGFR mutation status.

Methods: 131 treatment-naïve NSCLC patients from Guangdong, China was enrolled prospectively and BALF at initial diagnosis (59 EGFR-mutated and 72 wild-type cases) was collected. DNA was extracted for shotgun metagenomic sequencing. Alpha diversity was assessed using Observed Species and β-diversity was assessed using Bray-Curtis dissimilarity and Jensen-Shannon divergence (JSD), followed by Principal Coordinate analysis (PCoA). This was followed by KEGG Orthology (KO) and KEGG pathway enrichment analyses of differential species and metabolites. Spearman's rank correlation analysis was performed to evaluate associations between differential abundant microbial taxa and metabolites.

Results: EGFR-mutated cohort demonstrated significantly elevated α-diversity (Observed Species, $p = 0.007$) and β-diversity metrics (Bray-Curtis dissimilarity: $p = 0.004$; Jensen-Shannon divergence: $p < 0.001$) as well as in PCoA analysis compared to wild-type patients. In EGFR-mutated cohort, the significantly enriched($p<0.05$) genera were Pseudoalteromonas and Vibrio, whereas Fusobacterium and Rothia showed enrichment in wild-type cohort. Among tumor-immunity-related metabolites, adenosine was significantly enriched($p<0.05$) in EGFR-mutated cohort, whereas ellagic acid and valproic acid was accumulated in wild-type cohort. We summarized the top 20 differential genera and 51 differential metabolites between two cohorts. KO enrichment analysis of differential species($p<0.05$) showed that EGFR-mutated cohort were significantly enriched in proteins including hypoxia-inducible factor 1 (HIF-1) and inhibitor of apoptosis proteins (IAPs). In contrast, wild-type cohort exhibited enrichment($p<0.05$) in microtubule-related processes and mRNA splicing machinery. KEGG pathway analysis demonstrated significant enrichment($p<0.05$) of the prostate cancer pathway (PATH:ko05215) and NOD-like receptor signaling pathway (PATH:ko04621) in EGFR-mutated cohort whereas wild-type cohort indicated enrichment in ascorbate metabolism (PATH:ko00053) and spliceosome pathways (PATH:ko03040). KEGG enrichment analysis of differentially abundant metabolites($p<0.05$) revealed significant enrichment in pathways associated with Parkinson's disease, oxidative phosphorylation and neurodegenerative disorders. Notably, correlation analysis revealed positive associations($p<0.05$) between EGFR mutation-enriched genera and mutant-associated metabolites while negative correlations were observed($p<0.05$) with wild-type-associated metabolites.

Conclusions: To our knowledge, this is the first study to systematically analyze the BALF microbiota and metabolome profiles between EGFR-mutated and wild-type NSCLC patients. We identified differentially abundant microbial taxa and discriminatory metabolites, their mutation-specific enriched pathways and correlations.

PT1.06.03 Loss of MTAP Expression in Thymic Carcinomas: Insights From a Retrospective Multi-Institutional, Global Study

A.C. Roden[1], A. Churg[2], A. Sharma[3], D. Jain[3], P. Malik[3], S. Satapathy[3], M. Haberecker[4], F. Ardeshir- Larijani[5], S. Klebe[6], P. Baas[7]
[1]Mayo Clinic Rochester, Rochester/MN/USA ,[2]University of British Columbia, Vancouver/BC/CA ,[3]All India Institute of Medical Sciences, New Dehli/IN ,[4]University Hospital, Zurich/CH ,[5]Emory University, Atlanta/GA/USA ,[6]Flinders University, ADELAIDE/AU ,[7]Leiden University, Leiden/NL

Introduction: Due to the rarity of thymic carcinomas our understanding of molecular alterations is limited. While tumor mutational burden is low in many thymic carcinomas, various promising molecular alterations are increasingly reported. Identifying these molecular alterations could facilitate the development of targeted therapies, potentially expanding treatment options for patients. Recently a second-generation protein arginine methyltransferase 5 (PRMT5) inhibitor has shown promising activity in solid tumors with Methylthioadenosine Phosphorylase (MTAP) deficiency. MTAP-deficient tumors may also be susceptible to antifolates targeting de novo purine synthesis. Furthermore, in non-small cell lung cancer, loss of MTAP expression negatively predicts response to immune checkpoint inhibitors. Loss of MTAP expression and homozygous CDKN2A deletion, frequently observed in mesotheliomas and other neoplasms, have been identified in a subset of thymic carcinomas in a single institution study. We aimed to identify the prevalence of loss of MTAP expression and molecular alterations in thymic carcinomas in a global, multi-institutional study.

Methods: Institutional databases of members of the Rare Tumor Committee of the International Association for the Study of Lung Cancer (IASLC) were searched for thymic carcinomas. A representative tissue section was stained with the locally available immunohistochemical tests for MTAP (clones: 2G4, 1813, EPR 22570-76, 42-T, RBT-MTAP). A subset of cases stained with MTAP has been previously published. A subset of cases underwent molecular testing (Foundation One or a laboratory developed next generation sequencing test). Medical records were reviewed for demographics and outcome data which were recorded as deidentified information in a common spreadsheet. Institutional IRB-approvals were obtained.

Results: Sixty-four thymic carcinomas were included. Fifty-three patients with available medical history had a median age of 59.6 years (range, 28-84), 31 (58.5%) were male. Eight (of 64, 12.5%) thymic carcinomas showed loss of expression of MTAP, 5 (7.8%) additional thymic carcinomas revealed subclonal loss of MTAP expression. Details of MTAP expression and results of molecular testing (n=6) by thymic carcinoma subtype are summarized in Table 1.

Thymic Carcinoma Subtype	N=64 (%)	Complete Loss of Expression of MTAP n (%)	Subclonal Loss of Expression of MTAP n (%)	Preserved Expression of MTAP n (%)	Molecular Alterations[a]	TMB (mutations/ Mbp) Median (range)
Squamous cell carcinoma	29 (45.3)	4	0	25	3 (of 5, 60%) with molecular alterations[b]; *CDKN2A/B* (n=2), *TP53* (n=2), *FGFR3*, *BAP1*, *CREBBP*, loss of *CDKN2C*	2.5 (0-9)
Thymic Carcinoma, NOS	21 (35.6)	2	3	16		
Adenocarcinoma, NOS	3 (5.1)	0	2	1		
Small Cell Carcinoma	3 (5.1)	0	0	3		
Mucoepidermoid Carcinoma	2 (3.4)	0	0	2		
Adenosquamous Carcinoma	1 (1.7)	1	0	0		
Sarcomatoid carcinoma	2 (3.1)	1	0	1	1 (of 1, 100%) with molecular alterations, *EGFR* amplification, *ERBB2* amplification, *SETD2*	5
Undifferentiated Carcinoma	1 (1.7)	0	0	1		
Lymphoepithelial Carcinoma	1 (1.7)	0	0	1		
Typical carcinoid	1 (1.7)	0	0	1		

NOS, Not otherwise specified; Mbp, Megabase pair; [a]Molecular testing performed in 6 cases; [b]*MTAP* was not included in the molecular analysis of 1 case

In one case of thymic carcinoma with loss of MTAP expression no mutation of MTAP was found.

Conclusions: Our study suggests that 20% of patients with thymic carcinoma including squamous cell carcinomas, adenosquamous carcinomas, and sarcomatoid carcinomas, could potentially benefit from PRMT5 inhibitors or antifolate therapy. Loss of MTAP expression in thymic carcinomas may occur due to mechanisms other than mutation in the MTAP gene. Future studies will investigate whether loss of expression of MTAP may be associated with outcome.

PT1.06.04 Signatures of Functional CD8 T, Marginal Zone/Memory B and NK Cells in PBMCpredict Survivalin NSCLC Patients Receiving Chemoimmunotherapy

j. wang[1], Z. Hu[1], X. Zhang[1], S. Sun[1], Z. Wu[1], Y. Zhang[1], Y. Lin[1], H. Yu[1], X. Zhao[1], H. Wang[1], X. Wu[1], S. Huang[1], Q. Li[2], C. Zhu[2], T. Hu[2]
[1]Fudan University Shanghai Cancer Center, Shanghai/CN ,[2]Amoy Diagnostics Co., Ltd., Xiamen/CN

Introduction: Despite chemoimmunotherapy overcoming biomarker-based patient selection limitations, clinical evidence suggests variable treatment benefits. This study aimed to identify novel immune signatures derived from peripheral blood mononuclear cells (PBMCs) to predict survival in advanced non-small cell lung cancer (NSCLC) patients receiving chemoimmunotherapy.

Methods: We enrolled 133 treatment-naïve patients with advanced NSCLC who underwent first-line chemoimmunotherapy. Pre-treatment PBMC transcriptome sequencing was performed, and patients were randomly divided into discovery (n=81) and validation (n=52) cohorts. Using single-sample gene set enrichment analysis (ssGSEA) and Cox proportional hazards regression, we identified immune cell characteristics associated with prognosis and constructed a predictive model.

Results: Gene set analyses revealed significant associations between pre-treatment immune cell compositions and progression-free survival (PFS) and overall survival (OS) (P<0.05). CD8+ effector memory T cells, marginal zone B cells/activated memory B cells, adaptive natural killer cells-related genes expression were associated with improved PFS and OS. By integrating these T-cell, B-cell, and NK-cell module signatures, our comprehensive model effectively stratified patients into high- and low-risk groups with significant differences in survival outcomes. In the discovery cohort, median OS was significantly longer in the low-risk group (25.23 vs. 6.06 months, P<0.0001), as was median PFS (18.83 vs. 4.55 months, P=0.00015) (Fig 1a, b). These findings were confirmed in the validation cohort, with median OS (not reached vs. 8.36 months, P<0.0001) and median PFS (17.27 vs. 7.07 months, P=0.00013) (Fig 1c, d). Notably, our model demonstrated superior predictive performance compared to conventional PD-L1 expression thresholds (1% and 50%) for both PFS and OS (Fig 1e-p).

Conclusions: This novel PBMC-based immune signature model provides a robust, non-invasive approach for prognosticating outcomes in advanced NSCLC patients receiving first-line chemoimmunotherapy.

PT1.06.05 Enhancing Spread Through Air Spaces Diagnosis Using AI Diagnostician: A Multi-Center Study

H. Wu, Q. Zhang
Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Guangzhou/CN

Introduction: Spread Through Air Spaces (STAS) is closely related to the postoperative recurrence and prognosis of lung cancer, playing a pivotal role in guiding the selection of clinical treatments for early-stage lung cancer. However, the accurate pathological diagnosis of STAS remains challenging, hindered by the variety of STAS forms, limited specialized training among pathologists, and a global shortage of pathologists.

Methods: To address these challenges, we established the largest STAS datasets to date sourced from seven medical centers, and developed an innovative AI solution named AI Diagnostician for STAS (ADS).

Results: Leveraging 210 million pathological tiles from 1,586 whole-slide images (WSI), ADS demonstrates remarkable performance in identifying this unique and challenging tumor invasion pattern in clinical settings. Across the medical centers involved, ADS significantly outperforms conventional methods, achieving improvements in Area Under the Curve (AUC) ranging from 13.96% to 21.51% under fair settings. Moreover, ADS enhances the diagnosis sensitivity of junior pathologists by an average of 10.44%, while simultaneously reducing the average review time by 50.66%.

Conclusions: By augmenting diagnostic accuracy and efficiency in clinical practice for multicenter, ADS holds promise for enhancing the accurate diagnosis and treatment of lung cancer, ultimately improving patient outcomes.

Introduction: Pathologic response has become a surrogate of long-term outcomes following neoadjuvant chemotherapy, and most recently either the primary or secondary endpoint in phase II and III neoadjuvant immunotherapy clinical trials in non-small cell lung carcinoma (NSCLC). Although several recent retrospective studies have demonstrated the prognostic value of treatment response in lymph node metastases following neoadjuvant therapy, there remains no standardized or widely accepted guidance on how to evaluate pathologic response in resected lymph node specimens—either in clinical trials or routine clinical practice. In 2020, the International Association for the Study of Lung Cancer (IASLC) published detailed multidisciplinary consensus recommendations for standardization of gross processing and pathologic evaluation of surgically resected lung cancers treated with any type of neoadjuvant therapy. This recommendation provided a detailed guidance for the assessment of pathologic response in the primary tumor. The aim of the current project is to provide equally detailed guidelines on the evaluation of treatment response in the regional lymph nodes.

Methods: The IASLC Pathology Committee is conducting an interdisciplinary Delphi study, with broad representation from medical oncologists, thoracic surgeons, radiologists, and pathologists. The Delphi-Process is applied for the generation of the recommendations. A core group of pathologists has designed the questions to be answered and has drafted recommendations for voting by a large interdisciplinary project team. Feedback loops after voting ensure adaptation of the recommendations to gain final consent. Two to three rounds of voting are anticipated. According to the Delphi-SOP issued by the IASLC, consensus is defined as agreement of at least 85%.

Results: The core team has drafted 35 initial questions and has condensed them to 13 final recommendations for Delphi voting (see table). Those recommendations focus on interdisciplinary aspects, the definition of complete and major pathologic response (CPR, MPR) and application of TNM-staging when it comes to lymph node evaluation after neoadjuvant therapy, specificities of macroscopic and histological evaluation including slide preparation and the usage of immunohistochistry. The Delphi voting methodology is currently being executed.

Conclusions: The final IASLC interdisciplinary recommendations on the evaluation of lymph nodes resected after neoadjuvant therapy in NSCLC will be reported at the WCLC 2025. The proposed recommendations are intended to be practice-changing, providing a harmonized framework for evaluating regional lymph nodes that can be adopted in both clinical trials and real-world settings. Areas where consensus failed to be reached will equally be discussed, in order to stimulate future research.

Table: Recommendations for pathological response evaluation of resected lymph nodes after neoadjuvant therapy in NSCLC drafted for Delphi-voting.

Interdisciplinary Aspect	The surgical team should provide information about neoadjuvant therapy to the pathology laboratory to ensure proper processing and evaluation of the resection specimen.
Definitions of CPR and MPR	The term "Complete Pathologic Response (CPR)" is defined as no residual viable tumor in both the lung and the lymph nodes. Any viable tumor in lymph nodes precludes designation of CPR, even if the primary tumor shows no viable tumor cells.
	The term "Major Pathologic Response (MPR)" is defined as a treatment response of ≤10% viable tumor cells in the primary tumor. MPR can also be classified for the lung primary in the setting where the lung primary shows little or no viable tumor, but lymph nodes show viable metastatic carcinoma (ypT0, N1, 2, or 3).
Histologic Evaluation of Treatment Response in Lymph Nodes	For all patients who have undergone neoadjuvant therapy (regardless of regimen type), treatment response should be assessed across all sampled lymph nodes together using the IASLC-criteria established for the primary tumor and should be recorded separately to treatment response in the primary tumor. This involves estimating the percentages of viable tumor, stroma and necrosis within the tumor bed.
	If the tumor bed cannot be clearly identified, this limitation should be documented in the pathology report.
	Unweighted ("eyeball") estimation is acceptable for assessing treatment response in the lymph nodes.
	Whenever possible, the size of the largest metastatic deposit for each lymph node station should be reported.
	The presence of psammoma bodies or acellular mucin without viable tumor cells should not be regarded as viable tumor.
Staging	The general TNM staging, and R status assessment principles should continue to be applied.
	Treatment response in cases where the primary tumor directly extends into lymph nodes should be included in the evaluation of the primary tumor bed but staged as lymph node metastases in accordance with TNM general principles.
Macroscopic Aspects and Slide Preparation	All intraparenchymal lymph nodes in the main lung resection specimen as well as separately submitted lymph node stations should be entirely submitted for histologic evaluation. Exceptionally, if there is a very large metastasis (> 2 cm), the lymph node can be bisected and the central slice through the tumor can be submitted in designated cassettes.
	If a tumor bed is suspected but no viable tumor cells are detected in the initial histologic sections, deeper levels may be considered for further evaluation.
Use of IHC in Lymph Node Evaluation	Routine immunohistochemistry (IHC) in cases lacking morphological evidence of viable tumor cells is not recommended. In selected cases, however, immunohistochemistry (e.g., cytokeratin) may be used to confirm the presence of viable tumor cells suspected on H&E slides.

PT1.07.02 Neoadjuvant Ensartinib for ALK-Positive (ALK+) Non-Small Cell Lung Cancer (NSCLC): A Multicenter, Real-World Study

X. Zhang[1], S. Xie[2], G. Qiang[3], J. Ma[4]
[1]Shaanxi Cancer Hospital, Xi'an/CN ,[2]The Fouth Hospital of Hebei Medical University, Shijiazhuang/CN ,[3]Peking University Third Hospital, Beijing/CN ,[4]Harbin Medical University Affiliated Cancer Hospital, Harbin/CN

Introduction: Neoadjuvant-targeted therapies provided more opportunities for achieving a cure in patients with NSCLC. Notably, anaplastic lymphoma kinase (ALK) inhibitors in the neoadjuvant setting for ALK+ NSCLC have demonstrated promising efficacy and favorable tolerability profiles. Ensartinib is a novel, potent, and highly selective ALK inhibitor that has been approved for first-/second-line treatment of advanced ALK+ NSCLC. However, its application as a neoadjuvant therapy is supported by limited studies. This study aims to evaluate the efficacy and safety of ensartinib as neoadjuvant therapy for ALK+ NSCLC in a real-world setting. Herein, we primarily reported the outcomes of the retrospective cohort.

Methods: This study included patients aged ≥18 years with histologically confirmed resectable, stage II-III NSCLC who were ALK+, and had previously received neoadjuvant treatment with ensartinib, either as monotherapy or in combination with chemotherapy. Outcomes included major pathologic response (MPR), pathological complete response (pCR), objective response rate (ORR), disease-free survival (DFS), 2-year DFS rate, overall survival (OS), and safety.

Results: A total of 9 patients (median age, 61 years [range, 36-74]) with ALK+ NSCLC were included in this study; of whom, the majority were male (66.7%), diagnosed with lung adenocarcinoma (88.9%), and had an ECOG PS of 0 (55.6%). All patients (100.0%) underwent R0 resection. MPR and pCR rates were 66.7% (95% CI, 29.9%-92.5%) and 44.4% (95% CI, 13.7%-78.8%), respectively. No complete responses were observed, 7 patients (77.8%) achieved partial response, resulting in an ORR of 77.8% (95% CI, 40.0%-97.2%). Adverse events (AEs) occurred in 7 patients (77.8%), including rash (77.8%), white-cell count decreased (22.2%), dysgeusia (11.1%), and pruritus (11.1%). Only one patient (11.1%) experienced a grade ≥ 3 white-cell count decreased. No patients had grade ≥ 3 treatment-related AEs.

Conclusions: Neoadjuvant ensartinib demonstrated a promising antitumor activity in ALK+ NSCLC with high rates of MPR, pCR, and ORR, along with acceptable tolerability.

PT1.07.03 Adjuvant Osimertinib in IB-IIIB NSCLC with Uncommon EGFR Mutations (Admin): Mutation Profile and ctDNA Dynamics

C. Liu[1], X. Leng[2], D. Yue[3], G. Zhao[4], C. Cheng[5], G. Li[6], N. Liang[7], J. Zhao[8], S. Liu[9], M. Wu[10], J. Wang[10], L. Liu[1]
[1]West China Hospital, Sichuan University, Chengdu/CN ,[2]Sichuan Cancer Hospital, Chengdu/CN ,[3]Tianjin Medical University Cancer Institute and Hospital, Tianjin/CN ,[4]Ningbo No.[2] Hospital, Ningbo/CN ,[5]First Affiliated Hospital of Sun Yat-sen University, Guangzhou/CN ,[6]Yunnan Cancer Hospital, Kunming/CN ,[7]Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing/CN ,[8]The First Affiliated Hospital of Soochow University, Suzhou/CN ,[9]Fujian Provincial Cancer Hospital, Fuzhou/CN ,[10]AstraZeneca, Shanghai/CN

Introduction: Uncommon epidermal growth factor receptor mutations (EGFRm) constitute a heterogeneous group of mutations within exons 18 to 21, comprising approximately 10% to 20% of all EGFRm. Although osimertinib has demonstrated impressive efficacy in treating common EGFRm NSCLC, its efficacy in uncommon EGFRm NSCLC remains incompletely characterized. ctDNA monitoring could detect the molecular dynamics in uncommon EGFRm NSCLC.

Methods: The ADMIN study (NCT05546866) is an open-label, prospective, multicenter, single-arm trial that enrolled patients with stage IB-IIIB NSCLC harboring uncommon EGFRm (G719X, S768I, L861Q, or de novo T790M), who received adjuvant osimertinib (80 mg once daily) with or without prior adjuvant chemotherapy. Whole-exome sequencing (WES) was performed on primary tumor tissue to identify somatic mutations, and a personalized, tumor-informed ctDNA assay was utilized to monitor molecular residual disease (MRD) dynamics at baseline (before adjuvant osimertinib, D1) and after 12 weeks (wk-12) of adjuvant osimertinib. Quantitative analysis of MRD was conducted by measuring the concentration of haploid genome equivalents per milliliter (hGE/mL).

Results: A total of 51 NSCLC patients with uncommon EGFRm were enrolled. The mutation profile and relevant characteristics were presented in Figure 1. 43 pts had evaluable plasma ctDNA status at both D1 and wk-12 time point, comprising 23 males and 20 females with a median age of 66 years old. MRD positive rate was 23.3% (10/43) and mean level of ctDNA was 1.81 hGE/mL at D1 and reduced to 13.9% (6/43) and 0.05 hGE/mL at wk-12. 50% (5/10) of patients had ctDNA clearance (MRD positive to negative) after 12 weeks osimertinib treatment. 18.6%(8/43)of patients were plasma EGFRm positive at baseline. Plasma EGFRm clearance was observed in 62.5% (5/8) patients. In three patients without EGFRm clearance, variant allele frequency (VAF) of EGFRm was also largely decreased.

Conclusions: 12 weeks of osimertinib treatment could facilitate ctDNA clearance in stage IB-IIIB NSCLC with uncommon EGFRm. Long-term follow-up is ongoing to further investigate the association between ctDNA status and recurrence.

PT1.07.04 Radiomics Model Based on Synthesized PET for Predicting Neoadjuvant Therapy Pathologic Response in NSCLC (CPT-LC-NEO Trial)

H. Zhou, M. Weng, M. Li, H. Liu, L. Yao, S. Wu, G. Liao, C. Cai, R. Liu, Y. Lu
Department of Thoracic Surgery, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou [510080], China., Guangzhou/CN

Introduction: Neoadjuvant immunochemotherapy has become a cornerstone in lung cancer treatment, significantly improving patient prognoses. However, substantial inter-individual variability in therapeutic response and limitations in PET imaging hinder accurate pathological response prediction. To overcome these challenges, we propose a GAN-based framework that integrates cross-modal image synthesis and multimodal feature fusion, addressing incomplete clinical imaging data and single-modality limitations to establish a novel predictive paradigm for NSCLC neoadjuvant therapy.

Methods: A total of 729 NSCLC patients were enrolled and stratified into a source domain pre-training group (SDPG) and a target domain fine-tuning group (TDFG). An enhanced Pix2PixHD GAN was utilized to develop a CT-to-PET synthesis model (CPT-NeoIO). In the TDFG cohort, various machine learning models were employed to construct and validate single-modality and multimodal pathological response prediction models based on synthetic PET images. Subsequently, synthetic PET images were generated for 91 resectable NSCLC patients with only pre-treatment CT data, and an XGBoost-based predictive model was established to assess the impact of cross-modal PET generation and multimodal fusion on predictive performance (Figure 1.A).

Results: The CPT-NeoIO model generated PET images with high structural fidelity (SSIM = 0.946) and minimal reconstruction error (MSE = 0.017, IQR: 0.012-0.021). A Turing test demonstrated that 73% of the synthesized images were rated as high quality by clinical physicians. In predicting neoadjuvant therapy response, synthetic PET images achieved performance comparable to conventional imaging, and the multimodal fusion model outperformed single-modality models. Notably, the predictive efficacy of the multimodal model based on synthetic PET/CT closely matched that of real PET/CT (AUC = 0.796 vs. 0.791, p = 0.589) (Figure 1.B). Furthermore, in the validation cohort, incorporating synthetic PET into the multimodal model enhanced predictive accuracy (AUC increase from 0.57 to 0.72, Δ = 0.15, p = 0.002), demonstrating the efficacy of cross-modal synthesis and feature integration (Figure 1.C).

Conclusions: Our findings underscore the potential of GAN-based CT-to-PET synthesis in addressing PET imaging limitations while significantly improving the prediction of pathological response to neoadjuvant therapy in NSCLC through multimodal feature fusion. This approach holds substantial clinical translational value, offering a non-invasive, cost-effective, and accessible alternative for treatment stratification.

PT1.08.01 Neoadjuvant Almonertinib Followed by Chemo-Immunotherapy in II-IIIB EGFR-TKI, Interim Analysis of a Single Arm, Phase II Study (NEOVADE)

J-t. Lin, W-z. Zhong
Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University,, Guangzhou/CN

Introduction: Neoadjuvant EGFR-TKIs has revealed superior efficacy and disease-free survival (DFS) in resectable II-IIIB NSCLC, however, unmet needs remained in major pathological response (MPR) and overall survival (OS). This study aimed to explore the efficacy and mechanisms of neoadjuvant almonertinib followed by combination of immunotherapy and chemotherapy in II-IIIB NSCLC.

Methods: In this single arm, phase II study (NCT06300424), we tend to enroll 32 patients with untreated II-IIIB NSCLC to receive 110mg of almonertinib, followed by adebrelimab and chemotherapy every 3 weeks for 3 cycles before surgery. Primary end point was MPR.

Results: This study has enrolled 23 patients at the time of March 31, 2025, and 13 patients has undergone surgery, 1 patient discontinued 3rd chemo-immunotherapy and surgery. Overall response rate was 64.3% (9/14). MPR rate was 35.7% (5/14), including 2 (14.3%) patients with complete pathological response (CPR), N downstage was found in 50.0% (7/14) of patients. Twenty-one patients will finish neoadjuvant therapy and surgery as of July 30, 2025, further updated data will be presented at the Conference.

Conclusions: Neoadjuvant almonertinib followed by chemo-immunotherapy maybe a potential efficacious treatment for II-IIIB EGFR-NSCLC.

PT1.08.02 5-Y Outcomes of Stereotactic Ablative Radiotherapy in 101 Unresectable La-Nsclc Patients:The START-NEW-ERA Phase II Trial

F. ARCIDIACONO[1], P. Anselmo[1], M. Casale[1], G.A. Viani[2], C. Zannori[3], F. Loreti[4], V. Tassi[5], B. Enrico[6], A. Guida[3], M. Nunzi[6], L. Ricci[7], L. Lo Conte[4], G. Bellezza[7], M. Ragusa[5], M. Italiani[1], E. Maranzano[1], F. Trippa[1]
[1]Radiotherapy Oncology Centre "S. Maria" Hospital, Terni/IT ,[2]Radiotherapy Service Hospital das Clinicas of the Sao Paulo State University (UNESP) Medical School, Botucatu/BR ,[3]Oncology Centre "S. Maria" Hospital, Terni/IT ,[4]Nuclear Medicine Centre "S. Maria" Hospital, Terni/IT ,[5]Thoracic Surgery Centre "S. Maria" Hospital, Terni/IT ,[6]Radiology Centre "S. Maria" Hospital, Terni/IT ,[7]Pathology Centre "S. Maria" Hospital, Terni/IT

Introduction: In the early analysis of START-NEW-ERA phase II trial (Clinical trials.gov NCT05291780), stereotactic ablative radiotherapy (SAbR) had optimal local control (LC) and promising OS without ≥G3 toxicity in 50 unresectable LA-NSCLC patients unfit for concurrent chemo-radiotherapy (1). Here we report the 5-year outcomes of SAbR in 101 unresectable LA-NSCLC.

Methods: SAbR was delivered by V-MAT to primary tumor (T) and regional nodes (N) based on PET-CT. Simultaneous integrated boost (SIB) was optimized to differentiate the dose for T and N. Moreover, when target volume overlapped organs at risk (OAR) the simultaneous integrated protection (SIP) technique was implemented to lower the dose to the part of planning target volume closest to the critical OAR. Neoadjuvant ChT was prescribed in fit patients. After PACIFIC trial publication PD-L1 ≥1% received durvalumab after SAbR. The co-primary study endpoints were LC and safety. Hepilor gel and Kariosyte mouthwash were recommended in order to prevent dysphagia and esophagitis.

Results: Between December 2015 and August 2024, 101 unresectable LA-NSCLC patients unfit for concurrent ChT-RT were enrolled. Median age was 73 years (45-90). Histology was adenocarcinoma in 66% and squamous cell carcinoma in 34%. The stage was IIB, IIIA, IIIB and IIIC in 12%,41%,33% and 14%. 55% had multiple nodes, 84% was had central/ultracentral T and 96% had T and/or N overlapping organs at risk (OAR). 44%, 31% and 26% received SAbR alone, ChT followed by SAbR and ChT followed by SAbR followed by durvalumab. Median dose was 45 Gy (35-60) and 40 Gy (35-50) in 5 daily fractions to T and N, respectively. After a median follow-up of 55 months (95% CI, 38 to 76) range (10-119 months), the median local recurrence (LR) free survival (FS) was not reached (95% CI, 8 to not reached). The 1-, 3- and 5- year LR-FS rates were 88 ± 3%, 69 ± 5% and 69 ± 5%, respectively. The median thoracic nodal recurrence (TNR)-FS was not reached (95% CI, to not reached). The 1-, 3- and 5- year TNR-FS rates were 83 ±4%, 63 ±5% and 63 ± 5%, respectively. The median distant progression-FS (d-PFS) was 54 months (95% CI, 20 months to 65). The 1-, 3- and 5- year d-PFS rates were 79 ±4%, 50± 5% and 47± 6%, respectively. The median PFS was 14 months (95% CI, 13 to 20). The 1-, 3- and 5- year PFS rates were 62±5%, 31±5% and 28 ±6%, respectively. The median OS was 50 months (95% CI, 42 to 73). The 1, 3, and 5-year OS rates were 88 ± 3%, 65 ± 5% and 41 ± 6%, respectively. 2% and 2% patients had experienced G3 lung and esophageal toxicity, respectively.

Conclusions: To our knowledge the START-NEW-ERA is the trial with more patients and longer follow-up investigating SAbR in LA-NSCLC. The 5-year outcomes confirm robust and sustained benefit in terms of safety and effectiveness suggesting SAbR as a great alternative in LA-NSCLC patients unfit for concurrent chemo-radiotherapy.1. Int J Radiat Oncol Biol Phys 2023;115(4):886-896. doi: 10.1016/j.ijrobp.2022.10.025.

PT1.08.03 Chemoradiation/Immunotherapy(IO) for Stageiii NSCLC: Timing of IO, and the Benefits/ Selection in Elderly & Black Patients

H. Eldib[1], R. Voland[1], J. Flickinger[2], M. DeCamp[3], M. Jamil[1], N. Chowdhury[1], J. Bastidas[1], M. Shenouda[1], Y. Shweihat[1], M. Valsecchi[4], A. Bir[1], T. Pacioles[1], D. Silbermins[1], M. Legenza[1], J. Varlotto[1]
[1]Marshall University, Huntington/WV/USA ,[2]University of Pittsburgh Medical Center, Pittsburgh/PA/USA ,[3]University of Wisconsin, Madison/ WI/USA ,[4]Marshall University, Marshall University/WV/USA

Introduction: Durvalumab was FDA approved as consolidation immunotherapy(IO) after concurrent chemo/radiation(CRT) in 2018 for the treatment of Non-small cell lung cancer(NSCLC). Our study investigates the timing of IO's association with OS, the % of patients receiving IO for each year, and whether IO affects prognostic factors as compared to the years prior to its approval.

Methods: The NCDB was queried for Stage III NSCLC patients (2016-2022) undergoing CRT (54-66Gy) +/- IO. Patients were grouped based on IO timing after CRT (0-14, 15-28, 29-42, >42 days), assuming a 45-day course of CRT. Propensity score matching compared OS between early (0-14 days) and late IO administration and age-adjusted OS. ANOVA and multivariable analyses assessed OS factors for CRT alone (2016/2017, N=13,034, B years) vs. CRT + IO (2018-2021, N=29,974, A years) and IO selection factors (2018-2022, N=36,519). Ages were divided into quintiles for analysis.

Results: Median follow-up was 42 months. IO use increased from 47.8% to 58.3% from 2018-2022. Significant favorable OS factors in the B years include the youngest age quintile, academic facility treatment, and lower cT stage. In the A years, significant favorable factors include the youngest age quintile, Black race, academic facility treatment, 0 Charlson Deyo Score (CDCC), and adenocarcinoma. In 2018-2022, factors associated significantly with less IO use were the oldest two age quintiles, community programs, CDCC 3, Black/White Hispanic race, and non-adenocarcinoma histology. Compared to early IO, the HR for OS for those receiving IO at 15-28, 29-42, and >42 days were 0.94 (0.87-1.01), 1.02 (0.94-1.10), and 1.01 (0.94-1.01), respectively with median OS ranging from 39.1- 42.6 months. Patients aged 71+ benefitted just as much from IO as those < 70 with HRs = 0.56(0.53 -0.59), 0.55(0.53-0.58), respectively.

Conclusions: Consolidative IO remains underutilized with only 58.3% receiving it in 2022 despite its known ability to increase OS/PFS. The timing of IO administration had no effect on OS, but IO positively affected OS even in those who receiving IO at times greater than allowed in the Pacific trial(> 42 days post CRT, median 61 days). Those greater than 70 benefit equally from IO as those younger and Blacks benefit more from IO than other races despites significantly less IO use in these groups. There needs to be increased IO usage, especially in Black and elderly patients.

[1]Institute for Research in Biomedicine Barcelona (IRB), Barcelona/ES ,[2]Bellvitge Biomedical Research Institute (IDIBELL), L'Hospitalet de Llobregat/ES ,[3]Catalan Institute of Oncology (ICO), L'Hospitalet de Llobregat/ES ,[4]University of Barcelona Bellvitge Campus, L'Hospitalet de Llobregat/ES ,[5]Bellvitge University Hospital, L'Hospitalet de Llobregat/ES

Introduction: Cachexia is a wasting condition that negatively impacts survival outcomes and quality of life. Across solid tumors, cachexia is highly prevalent, accounting for about half of patients with advanced cancer, including lung cancer. Nevertheless, cancer-associated cachexia is not captured by the national cancer statistics in any country and is seldom listed as the cause of death. It is mainly associated with advanced disease but can also occur in curable setting and might be reversed by successful treatment of the underlying cancer. We hypothesize that evaluating circulating non-invasive markers, such as cytokines, could help better understand the cachexia phenotype and identify potential interventions to improve the clinical management of these patients.

Methods: We conducted a prospective study that included 51 patients with stage III unresectable non-small cell lung cancer (NSCLC) that underwent concurrent chemoradiotherapy followed by immunotherapy. Body composition, metabolic parameters have been prospectively assessed, and blood was collected before and after completing chemoradiation. Patients were classified based on their cachexia status. Cachexia was defined as weight loss greater than 5%, or weight loss greater than 2% in individuals with body mass index (BMI) <20 kg/m2 or low skeletal muscle mass (Fearon criteria). Then, metabolic parameters, body composition metrics and the circulating levels of different cytokines were compared between the two groups.

Results: 27 patients (53 %) with stage III unresectable NSCLC had cachexia based on Fearon's criteria. Almost all women included in the study displayed cachexia, whereas men were evenly distributed across groups. The cachectic phenotype was significantly enriched in patients with poorer ECOG performance status, higher tumor stage, lower BMI values, higher reactive C protein blood levels, moderate to severe malnutrition, decreased caloric intake and decreased physical strength, based on dynamometer test. Patients with cachexia had worse PFS compared with those without (univariate HR (95%-CI) = 3.1 (0.9 - 10.9), p = 0.08). Regarding body composition, cachexia-classified patients showed less adipose tissue (i.e., lower subcutaneous, visceral and total adipose tissue index) and lower skeletal muscle index. We identified several cytokines that were elevated in the blood of patients with cachexia compared with their counterparts, such as CCL23, IL6, IL11, OSM or AGRP.

Conclusions: Cancer cachexia is frequent in stage III unresectable NSCLC and is associated with shorter PFS. We identified novel cytokines associated with cancer cachexia that might become new potential targets to overcome this debilitating condition.

PT1.08.05 Radioresistance of NSCLC Tumors Is Mediated by Immunosuppressive Cell Populations. Strategies to Sensitize Tumors by Targeting Innate Immunity

S. León[1,2,3], D. Serrano[1,2,4], N. Otegui[1,2,3], M. Redrado[1,4], E. Guruceaga[1], L. Montuenga[1,2,3,4], J.J. Aristu[5], A. Calvo[1,2,3,4]
[1]Center for Applied Medical Research (CIMA), Pamplona/ES ,[2]School of Medicine, University of Navarra, Pamplona/ES ,[3]CIBERONC, ISCIII, Madrid/ES ,[4]IDISNA, Pamplona/ES ,[5]University Clinic of Navarra, Madrid/ES

Introduction: Standard treatment for inoperable or unresectable stage I-III NSCLC includes stereotactic ablative radiotherapy (SABR) and concurrent chemo and radiotherapy, but locoregional recurrence occurs in 10%-30% of the patients. In the absence of distant metastasis, re-irradiation is the main curative-intent treatment option available for these patients. The tumor microenvironment (TME) plays a role in supporting tumor growth and resistance to cancer therapies. However, scarcity of immunocompetent lung cancer models to assess radioresistance in the context of re-irradiated tumors has hindered the study of the relevance of the TME in this process. In the present study, we have developed and characterized two murine lung adenocarcinoma models of radiation resistance in immunocompetent mice and evaluated the role of TME cell in radioresistance.

Methods: Two lung adenocarcinoma cell lines (Lacun3 and CMT167) were subjected to several rounds of irradiation (in vivo and in vitro) to generate their corresponding radioresistant cell lines (Lacun3 RR and CMT167 RR from now on). Resistance to radiation was tested in vivo and TME was analyzed with flow cytometry, in situ immunophenotyping, RNA sequencing (seq) and immune depletion experiments.

Results: We have successfully generated and characterized the Lacun3 RR and CMT167 RR models. Clonogenic and apoptotic assays confirmed that both Lacun3 RR and CMT167 RR were more resistant to radiotherapy than their parental cell lines. Downstream signaling cascades revealed increased pATR, pP38 and pP70-S6K levels in these cells, with higher sensitivity to pATR-targeting drugs. To validate the phenotype in vivo, different radiation schedules were tested for both models (3 x 8 Gy for Lacun3 RR; 5 x 5 Gy for CMT167 RR). In both cases we found that immunocompetent mice bearing radioresistant tumors were completely refractory to irradiation, unlike controls. RNAseq showed downregulation of STING, IFNα/β and IFNγ signaling, as well as reduced expression of proinflammatory cytokines, in irradiated Lacun3 RR tumors. Flow cytometry and/or in situ localization revealed decreased tumor infiltration of CD4+, CD8+, CD8+/PD-1+ and macrophages, as well as increase in T regulatory (Treg) cells and PMN-MDSC cells, in irradiated Lacun3 RR tumors. In irradiated CMT167 RR tumors, reduction in NK cells, CD4+ cells and macrophages, together with increase in Treg cells was observed. Depletion of CSFR1+ cells, Gr1+ cells or the STING/IFNα/β/γ axis with poly(I:C) + resiquimod in radioresistant tumors led to re-sensitization to radiotherapy. Co-depletion of CD8+/CD4+ lymphocytes led to resistance to radiotherapy in parental tumors. Injection of Lacun3 RR and CMT167 RR tumors in athymic nude mice (immunodeficient) resulted in radiotherapy sensitivity, similar to the one found for the parental tumors, thus stressing the role of the immune system in radioresistance.

Conclusions: Our results demonstrate that the immune system plays a key role in radioresistance, in the two immunocompetent mouse models that we have generated. Each radioresistant model has their own particular TME, suggesting that, depending on the TME, radioresistance can be mediated by different immune populations. Moreover, targeting the immunosuppressive myeloid population or restoring innate immunity can revert resistance to radiotherapy in NSCLC.

PT1.09.01 Chemoradiotherapy Plus Tislelizumab in Advanced or Metastatic NSCLC: A Prospective, Multicenter, Phase II Study

S. Lin[1,2], S-l. Xu[1], P-r. Ren[1], L-l. Zou[1], X-l. Zhang[1]
[1]The Affiliated Hospital of Southwest Medical University, Luzhou/CN ,[2]Nuclear Medicine and Molecular Imaging Key Laboratory of Sichuan Province, Luzhou/CN

Introduction: In recent years, the combination of chemotherapy and immune checkpoint inhibitors (ICIs) has significantly improved survival outcomes in patients with advanced non-small cell lung cancer (NSCLC). However, 30%-50% of patients still fail to benefit from this approach in clinical practice. Emerging evidence suggests that radiotherapy can synergize with chemotherapy and ICIs by modulating the tumor immune microenvironment (TIME). This triple-combination strategy may overcome current therapeutic limitations and expand the population responsive to immunotherapy.

Methods: We conducted a phase II study to evaluate the efficacy and safety of chemoradiotherapy plus tislelizumab in advanced or metastatic NSCLC. Thirty eligible patients were enrolled and received induction therapy consisting of:4 cycles of tislelizumab (200 mg Q3W), platinum-based doublet chemotherapy, Stereotactic body radiotherapy (SBRT, 40-50 Gy/3-5 f)or hypo-fractionated radiotherapy (HFRT, 30 Gy/1 f) The first cycle of chemotherapy and immunotherapy was administered 3-7 days after radiotherapy. Patients then received maintenance tislelizumab until disease progression or intolerable toxicity. Primary endpoint: 1-year progression-free survival (PFS) rate. Secondary endpoints: objective response rate (ORR), PFS, overall survival (OS), safety, tolerability, and exploratory biomarker analysis.

Results: As of March 2025, 30 patients had been enrolled. Key efficacy outcomes included:1-year PFS rate:53.0%,ORR:39.7%,Disease control rate (DCR):61.4%,Median PFS and OS data remain immature. Safety profile: Grade 3-4 adverse events (AEs): 2 patients (6.7%), including immune-related pneumonitis (3.3%) and immune-related heart failure (3.3%). Grade 1-2 AEs:19 patients (63.3%), most commonly hepatic dysfunction and granulocytopenia. Preliminary findings suggest that in bone metastasis patients treated with SBRT plus tislelizumab, elevated serum urea (Urea)and alkaline phosphatase (ALP) levels may serve as biomarkers for poor prognosis.

Conclusions: This study suggests that the triple-combination strategy (chemoradiotherapy plus immune checkpoint inhibitors) may represent a promising therapeutic approach for advanced NSCLC patients.

PT1.09.02 Double Lung Transplantation in Patients With Metastatic Lung-Limited Non-Small Cell Lung Carcinoma (NSCLC): A Case Series

Y.K. Chae, C. Kurihara, T. Demir, L.I-y. Chung, W. woo, C. Moloney, B. Sanson, R. Dwyer, C. Jung, A. Bharat
Northwestern University, Chicago/IL/USA

Introduction: The role of double lung transplantation (DLT) in patients with advanced bilateral lung-limited non-small cell lung cancer (NSCLC) has been a subject of debate. We present a prospective study involving patients who underwent DLT for this indication.

Methods: Patients treated with DLT for advanced bilateral lung-limited NSCLC were identified between September 2021 and December 2024 at Northwestern Memorial Hospital. All patients were enrolled in the DLT registry for lung-limited malignancies (DREAM) study cohort A (NCT05671887). Exclusion criteria included the presence of extrapulmonary disease. The indication for DLT was cancer refractory to available systemic treatments, with or without respiratory failure.

Results: Eleven patients with advanced bilateral lung-limited NSCLC were included; the median age was 62 years (range 37-71). Two patients (18%) were Asian, eight (73%) were White, one was Black (9%), Six (55%) were female, and three (27%) had a history of smoking. Seven patients (64%) had invasive mucinous adenocarcinoma, and four patients (36%) had invasive non-mucinous adenocarcinoma histology. The median number of pretransplant treatment lines was 3 (range 1-8). All patients experienced disease progression on standard-of-care treatments, with or without participation in clinical trials. The median duration of the waitlist for DLT was 18 days (range 5-414). There was no 30-day mortality. Only one patient experienced a recurrence at 18 months post-DLT, presenting with a 1 cm solid nodule, successfully treated with stereotactic body radiotherapy. Furthermore, the explant pathology revealed malignant cells in the mediastinal and hilar lymph nodes in two patients. With a median follow-up of 16 months (range 1-39), there were no cases of rejection, no patients required oxygen therapy, and all patients remained alive at the time of reporting.

Conclusions: Eleven patients with NSCLC underwent DLT successfully without experiencing any significant complications. All patients have survived, with one patient receiving curative treatment after a recurrence, while the remaining patients are currently under observation.

,[2]Geneplus-Beijing, Beijing/CN

Introduction: Cancer cell dormancy is a major contributor to cancer recurrence and therapeutic failure, as dormant cells evade both anticancer drugs and the host immune system. Although substantial progress has been made in understanding the mechanisms underlying dormancy, critical knowledge gaps remain. Recent studies have highlighted circulating tumor DNA (ctDNA) as a potential diagnostic tool for tumor dormancy. This study elucidates the dormancy characteristics of oligometastatic lung cancer across varying ctDNA statuses.

Methods: We conducted whole-exome and whole-transcriptome sequencing on primary tumor samples from 21 patients with induced-oligometastatic lung cancer, all of whom had undergone surgical resection following first-line systemic therapy with pathologically confirmed residual viable tumor cells exceeding 30%. High-depth ctDNA analysis was performed on matched blood samples. Tumors from patients with preoperative ctDNA-negative status were classified as dormant, whereas those with ctDNA-positive status were deemed proliferative.

Results: Compared to proliferative tumors, dormant tumors exhibited lower neoantigen numbers (P = 0.02) and neoantigen burden (P = 0.02). In all tumors, the incidence of neoantigen-related gene in-frame deletions in dormant tumors was significantly lower than in proliferative tumors (P = 0.001). Particularly, candidate neoantigen IKTSPKANK generated by EGFR Ex19 del (in-frame deletion in exon 19 mutation) in dormant tumors was selectively reduced. Furthermore, genes related to cell division pathway were significantly downregulated in dormant tumors. Finally, dormant tumors had a more immunosuppressive tumor microenvironment, including higher levels of M2 macrophages (P = 0.01) and regulatory T cells (P = 0.003) compared with proliferative tumors.

Conclusions: Oligometastatic lung cancer patients with pre-local treatment ctDNA-negative status exhibited dormant features, characterized by downregulated antigen presentation, dysregulated cell division, and a tumor microenvironment that suppresses immune effector functions. These findings provide critical insights for refining therapeutic strategies in the management of oligometastatic lung cancer.

PT1.09.04 Incomplete Cryoablation Promotes Recurrence and Progression of KRAS-Driven Lung Adenocarcinoma via the NF?B-CCL20-MAPK/MEK/ERK Axis

y. xing, C. Mu, Z. Liu, J. Huang
The First Affiliated Hospital of Soochow University, SuZhou/CN

Introduction: Cryoablation (CA) can serve as an alternative treatment for high-risk patients with KRAS-driven lung adenocarcinoma (LUAD) who are ineligible for surgical resection. However, incomplete CA and high postoperative local recurrence rates remain major challenges limiting its clinical application. The C-C motif chemokine ligand 20 (CCL20) is involved in LUAD processes such as epithelial-mesenchymal transition (EMT), cell proliferation, and migration. Nevertheless, whether CCL20 mediates the recurrence and progression of KRAS-driven LUAD after incomplete CA, as well as the underlying molecular mechanisms, remains unclear. This study constructs in vitro and in vivo models of incomplete cryoablation to demonstrate that incomplete ablation upregulates CCL20 expression in residual KRAS-driven LUAD cells, thereby activating the MAPK/MEK/ERK pathway and promoting tumor recurrence and metastasis. The findings may reveal novel therapeutic targets for combination therapy with cryoablation, offering new strategies for post-CA management.

Methods: Orthotopic KRAS-driven LUAD xenografts and primary cell lines were subjected to incomplete cryoablation using a clinical-grade cryoablation device (in vivo) and a controlled liquid nitrogen spray system (in vitro), respectively. RNA-seq of residual tumors/cells revealed the conserved dysregulated gene and pathways. Potential key dysregulated genes were subjected to transcription factor and binding site prediction using UCSC and JASPAR databases, followed by dual-luciferase reporter assay, functional validation through loss-of-function analysis (siRNA/ CRISPR-Cas9-based editing), downstream signaling analysis (RT-qPCR/Western Blot/ Immunofluorescence) and Functional characterization of cells and mouse xenografts.

Results: Following incomplete ablation, residual KRAS-driven LUAD cells exhibited significantly enhanced proliferation and migration capabilities. Correspondingly, KRAS-driven LUAD mouse xenografts showed post-CA recurrence, progression, and metastasis. Integrated analysis combining whole-transcriptome sequencing of residual tumor cells and transcription factor prediction via the JASPAR and UCSC databases identified NF-κB and CCL20 as significantly upregulated molecules after incomplete cryoablation. Additionally, NF-κB was predicted to transcriptionally regulate CCL20 expression after incomplete CA, which was further confirmed by dual-luciferase reporter assays. Through NF-κB siRNA transfection, NF-κB knockout and overexpression stable cell lines, and functional validation, we demonstrated that NF-κB upregulates CCL20 expression post-incomplete CA, and CCL20 subsequently activates the cytoplasmic MAPK/MEK/ERK signaling cascade via phosphorylation, promoting tumor proliferation, migration, and clonal survival. Ultimately, the NF-κB-CCL20-MAPK/MEK/ERK axis drives local recurrence, disease progression, and lung metastasis in mouse models.

Conclusions: We establish that incomplete cryoablation drives KRAS-driven LUAD recurrence and metastasis via CCL20-mediated MAPK/MEK/ERK activation, revealing a targetable mechanism for post-procedural combination therapies.

PT1.09.05 Preclinical Safety Assessment of a Conformable Electrode for Bronchoscopy-Guided Radiofrequency Ablation

M.J. Kim[1], W. Ji[1], J. Seo[2], C. Lee[2], J. Kim[2], W. Kim[3], C.G. Kang[4], C-M. Choi[1]
[1]Asan Medical Center, Seoul/KR ,[2]Research Institute of Tau Medical, Yangsan South Korea, Yangsan/KR ,[3]Mobility System Group, Korea Institute of Industrial Technology, Daegu/KR ,[4]Vasflex Co., LTD, Daegu/KR

Introduction: The Conforming Ablation of Radiofrequency Out of a Liquid Metal (CAROL) technique is a novel bronchoscopic treatment for peripheral lung tumors using a conformable liquid metal electrode. We aimed to evaluate its toxicological safety for bronchoscopy-guided endobronchial radiofrequency ablation in a preclinical animal model.

Methods: The liquid metal electrode (75% gallium, 25% indium; E-GaIn) was administered via the CAROL system and evaluated in Sprague-Dawley rats. Body weight, CBC, blood chemistry, and serum levels of gallium (Ga) and indium (In) were assessed over 13 weeks. Subjects were classified into four groups: control, low, medium, and high dose (5×, 7.5×, 10× human-equivalent dose, respectively).

Results: A total of 48 rats were assigned to each group (12 per group; 6 males and 6 females). All animals showed consistent body weight increases with no significant differences between groups (control: 445.24±106.82 g; low dose:447.89±105.91 g; medium dose:450.27±115.55 g; high dose:439.72±97.87 g, P = 0.737) (Figure 1). CBC and blood chemistry parameters remained within normal physiological ranges. Serum Ga and In increased dose-dependently, but remained negligible in terms of safety. The AUC values for Ga and In were as follows: low dose, 0.04±0.03 μg/mL and 0.00032±0.00065 μg/mL; medium dose, 0.06±0.4 μg/mL and 0.00103±0.00183 μg/mL; high dose, 0.16±0.14 μg/mL and 0.00253±0.00306 μg/mL (Figure 2). Additionally, further tissue distribution analysis showed that gallium was detected in major organs in a dose-dependent manner, with the highest concentration in the lungs, followed by the spleen, and no toxic responses were observed in any organs.

Conclusions: Our preclinical study demonstrated that direct endobronchial administration of the conformable liquid metal electrode (E-GaIn) had no adverse effects on growth, with E-GaIn detected at negligible systemic levels without any toxic responses. These findings support the CAROL technique as a promising and safe bronchoscopic treatment for peripheral lung tumors.

PT2.10.01 Incidence and Severity of Interstitial Lung Disease Associated With Antibody-Drug Conjugates in NSCLC and SCLC: A Meta-Analysis

R. Paredes de la Fuente[1], T. Eris[1], W. He[1], L. Weintraub[1], R. Borea[2], F. Drago[2], Y. Fujiwara[3], K. Santana[1], A. Russo[4], G. Nigita[2], C. Rolfo[2]
[1]Icahn School of Medicine at Mount Sinai, New York/NY/USA ,[2]The Ohio State University Comprehensive Cancer Center, Columbus/OH/USA ,[3]Roswell Park Comprehensive Cancer Center, Buffalo/NY/USA ,[4]Humanitas Istituto Clinico Catanese, Misterbianco Catania/IT

Introduction: Antibody-drug conjugates (ADCs) have transformed the treatment landscape of multiple malignancies, including non-small cell lung cancer (NSCLC) and Small Cell Lung Cancer (SCLC). However, pulmonary toxicity, particularly interstitial lung disease (ILD), has emerged as a clinically significant adverse event. While clinical trials often exclude patients with preexisting pulmonary comorbidities, real-world populations with NSCLC and SCLC frequently carry risk factors such as smoking history and prior lung injury. To better quantify the pulmonary safety profile of ADCs in lung cancer, we conducted a meta-analysis of ILD incidence, severity, and treatment discontinuation due to ILD.

Methods: We performed a systematic literature review and meta-analysis following PRISMA guidelines, including phase I-III clinical trials of ADCs in patients with NSCLC and SCLC. Databases searched included MEDLINE, Embase, and Cochrane CENTRAL. Eligible studies reported the incidence of ILD (any grade, grade ≥3, and treatment discontinuation due to ILD) using CTCAE criteria. Pooled incidence estimates and 95% confidence intervals (CI) were calculated using a random-effects model with logit transformation. Heterogeneity was assessed via the I^2 statistic and τ^2. Subgroup analyses were performed by ADC agent and payload type. Meta-regression was used to evaluate the independent contributions of payload versus ADC.

Results: We identified 18 clinical trials in NSCLC (N = 2,123 patients) and 5 trials in SCLC (N = 555 patients) evaluating the safety of ADCs with respect to ILD. In NSCLC, the highest pooled incidence of any-grade ILD was seen with patritumab deruxtecan (23%) and trastuzumab deruxtecan (22%), followed by datopotamab deruxtecan (9%), telisotuzumab vedotin (7%), and sacituzumab govitecan (1%). For grade ≥3 ILD, trastuzumab and patritumab deruxtecan again demonstrated the highest pooled rates at 6-7%, whereas other ADCs ranged from 0-3%. Treatment discontinuation due to ILD in NSCLC was highest with telisotuzumab vedotin combined with erlotinib (36%), followed by trastuzumab deruxtecan (9%) and patritumab deruxtecan (7%). In contrast, datopotamab deruxtecan (4%) and sacituzumab govitecan (0%) showed lower discontinuation rates. In SCLC, any-grade ILD incidence was 8% with rovalpituzumab tesirine, with no reported grade ≥3 ILD events. No ILD-related treatment discontinuations were reported in the included SCLC trials. Meta-regression indicated that ADC agent explained a larger proportion of between-study variance in ILD incidence (R^2 = 74%, p = 0.006) compared to payload type (R^2 = 26%, p = 0.007). In a combined model, ADC identity remained the only independent predictor of ILD risk.

Conclusions: ILD is an important adverse event associated with ADC therapy in lung cancer, with risk varying considerably by agent. HER2/HER3-targeted, deruxtecan-containing ADCs demonstrated the highest ILD rates, while other ADCs such as sacituzumab govitecan had minimal reported toxicity. These findings highlight the need for agent-specific ILD monitoring and support the consideration of ADC design, including target and payload, when evaluating pulmonary safety and guiding clinical decision-making.

Introduction: The first-in-class c-Met (also known as MET) protein-directed antibody-drug conjugate (ADC) telisotuzumab vedotin (Teliso-V) is composed of the monoclonal antibody telisotuzumab conjugated to the microtubule inhibitor monomethyl auristatin E (MMAE). Peripheral neuropathy (PN) is a known cumulative toxicity associated with MMAE ADCs. In the phase 2 LUMINOSITY trial (NCT03539536), PN was observed in patients treated with Teliso-V. We present data from LUMINOSITY on PN occurrence and severity, and efficacy outcomes in patients who developed PN.

Methods: Patients (≥18 years) with locally advanced/metastatic c-Met protein-overexpressing EGFR-wildtype non-squamous NSCLC who received prior therapy were treated with 1.9 mg/kg Teliso-V every 2 weeks. c-Met protein overexpression (by immunohistochemistry clinical trial assay for MET [SP44] [Roche]) was defined as ≥25% tumor cells with 3+ staining intensity (c-Met intermediate: 25-<50% 3+; c-Met high: ≥50% 3+). The primary endpoint was overall response rate by independent central review per RECIST v1.1. Adverse events were reported using MedDRA Preferred Terms; analyses are presented on PN summarized on the basis of standardized MedDRA queries (SMQ narrow).

Results: A total of 168 patients who received Teliso-V at 1.9 mg/kg every 2 weeks were included in the analyses (data cutoff: 21 February 2024). Overall, 74 (44.0%) patients experienced any-grade PN and 17 (10.1%) had grade ≥3 PN (treatment-related PN per investigator: any grade in 69 [41.1%]; grade ≥3 in 16 [9.5%] patients). Median time to PN onset was 103 days (range: 1-472). For 20 (11.9%) patients, PN led to treatment discontinuation. PN events leading to discontinuation occurred at a median 238.5 days (range: 57-519). Median exposure to Teliso-V was longer for patients with PN grade ≥3 (8.3 months, range: 1.4-11.3) versus patients without PN grade ≥3 (4.2 months, range: 0.03-28.8). Efficacy outcomes for patients with and without PN grade ≥3 are in the Table.

Conclusions: Although a common event in patients treated with Teliso-V, PN is a cumulative toxicity, as evidenced by the late onset of these events (median time to PN events leading to discontinuation of nearly 8 months). Patients with grade ≥3 PN (n=17) had a longer median duration of treatment and improved efficacy outcomes compared with those without grade ≥3 events (n=151). Although the number of patients with grade ≥3 PN was limited, these findings suggest that patients who develop these events are generally patients who remain on treatment for an extended time, indicating they are deriving benefit from Teliso-V.

Table. Efficacy outcomes in patients with and without grade ≥3 peripheral neuropathy

Introduction: HLX43, a novel PD-L1-targeted antibody-drug conjugate (ADC), exhibits dual mechanisms: immune checkpoint blockade and payload-mediated cytotoxicity. Preclinical data showed tumor regression of HLX43 in PD-(L)1 inhibitor-resistant non-small cell lung cancer (NSCLC) and esophageal squamous cell carcinoma models. This study aims to evaluate the safety, tolerability, and preliminary efficacy of HLX43 in patients with advanced solid tumors who have failed standard therapies.

Methods: This multicenter Phase I study evaluated HLX43 in two parts: the dose-escalation Phase (Ia) enrolled patients with advanced solid tumors to receive intravenous injections of HLX43 at 0.5, 1, 2, 2.5, 3, and 4 mg/kg every three weeks (Q3W). The primary objectives of this part were to assess dose-limiting toxicities (DLTs) and determine the maximum tolerated dose (MTD). The dose-expansion Phase (Ib) assessed the safety and preliminary efficacy (objective response rate [ORR]) of HLX43 in NSCLC patients refractory to standard therapies. Patients were administered HLX43 at doses of 2, 2.5, or 3 mg/kg Q3W to determine the recommended Phase II dose (RP2D).

Results: From November 08, 2023 to January 09, 2025, a total of 114 patients were screened, of whom 85 patients met the eligibility criteria and received HLX43. In Phase Ia, 21 patients with advanced solid tumors were enrolled, while in Phase Ib, 64 NSCLC patients were recruited across three cohorts (2, 2.5, and 3 mg/kg). The median age of the enrolled patients was 60.0 years, with 52 males (61.2%). This study enrolled patients with NSCLC (n=76), thymic squamous cell carcinoma (n=4), cervical cancer (n=1), nasopharyngeal carcinoma (n=1), head and neck squamous cell carcinoma (n=1), uterine carcinosarcoma (n=1), and small cell lung cancer (n=1). Notably, 88.2% (75/85) of patients failed prior checkpoint inhibitor (CPI) therapy. In Phase Ia, one DLT event involving febrile neutropenia was observed in the 4 mg/kg group. Treatment-related adverse events (TRAEs) were reported in 95.2% of patients, mostly Grade 1-2. Grade ≥3 TRAEs occurred in 5 patients (23.8%), all from the 3 and 4 mg/kg cohorts, most frequently decreased neutrophil count (19%), decreased white blood cell count (19.0%) and anemia (14.3%). Among the 76 NSCLC patients (69 efficacy-evaluable), ORR was 31.9% (22/69), with a disease control rate (DCR) of 87.0% (60/69). Subgroup analyses demonstrated promising efficacy of HLX43 in specific populations: the 2 mg/kg and 2.5 mg/kg cohorts in Phase Ib achieved ORRs of 38.1% (8/21) and 33.3% (7/21), respectively; CPI-refractory NSCLC patients (n=61) showed an ORR of 32.8% (20/61); EGFR wild-type non-squamous NSCLC patients (n=19) had an ORR of 47.4 % (9/19); PD-L1-positive NSCLC patients (n=50) exhibited an ORR of 32.0% (16/50) while PD-L1-negative/unknown patients (n=19) achieved an ORR of 31.6% (6/19). In the 2 mg/kg group of Phase Ib, the median progression-free survival was 5.4 months (95% CI: 4.0-not evaluable). Additional data will be revealed with extended follow-up.

Conclusions: HLX43 demonstrated a manageable safety profile and preliminary antitumor activity in patients with advanced NSCLC who were refractory to standard therapies, including those who had progressed after treatment with PD-(L)1 inhibitors. Enrollment in the Phase Ib expansion cohort is ongoing.

Introduction: TQB2102 is a novel biparatopic antibody-drug conjugate (ADC) designed to target two non-overlapping epitopes in ectodomain 2 and 4 of HER2. Conjugated to a topoisomerase I inhibitor payload with a drug-to-antibody-ratio (DAR) of 6, this innovative design enhanced HER2 internalization and improve therapeutic efficacy in preclinical models. Compared to single-target HER2 ADCs, TQB2102 provides better tumor uptake, particularly in heterogeneous non-small-cell lung cancer (NSCLC) with varied HER2 expression profiles.

Methods: This open-label phase II study evaluated TQB2102 in patients with locally advanced or metastatic HER2 aberration NSCLC who had received at least one prior line of therapy. Enrolled patients received TQB2102 as monotherapy at 7.5mg/kg intravenously every 3 weeks. The primary endpoint was objective response rate (ORR) and secondary objectives were disease control rate (DCR), progression-free survival (PFS) and safety.

Results: As of March 31,2025, 59 patients were enrolled in three cohorts: cohort 1 (HER2 mutation, N=37), cohort 2 (HER2 gene amplification or protein overexpression, IHC 2+/3+, N=11) and cohort 3 (co-occurrence of HER2 aberration and EGFR mutation, N=11). Median age was 57 years (range 34-73), with 55.9% male, and 62.7% having an ECOG PS of 1. Among the 51 response-evaluable patients, 32 (62.7%) achieved partial response. The ORR was 61.1% in cohort 1 (22/36), 44.4% in cohort 2 (4/9), and 100% in cohort 3 (6/6). Responses were observed as early as the first tumor assessment in 23 of 32 responders. Notably, one patient in cohort 1 achieved complete response in the target lesion after 4 cycles of treatment. The disease control rate was 97.2%, 88.9%, and 100% in cohort 1, 2 and 3, respectively. In patients with baseline brain metastasis, the ORR was 62.5%. The most common treatment related adverse events (TRAEs) were leukopenia (64.9%), nausea (63.2%), anemia (61.4%), thrombocytopenia (56.1%), neutropenia (54.4%), and decreased appetite (54.4%). Grade ≥3 TRAEs occurred in 66.7% patients, with anemia (17.5%), thrombocytopenia (15.8%), neutropenia (14.0%), and leukopenia (14.0%) being the most frequent. Interstitial lung disease was reported in 2 patients (one grade 2 and one grade 3). Data on progression-free survival (PFS) is not yet mature, we will report the updated PFS data at the conference.

Conclusions: TQB2102 demonstrated robust efficacy, particularly in patients with HER2 mutation and concurrent HER2/EGFR aberration NSCLC. The favorable safety profile supports further investigation of TQB2102 in combination therapy trials and biomarker-driven studies to optimize its clinical application for this challenging patient population.

Introduction: Non-small cell lung cancer (NSCLC) in patients who have never used tobacco is associated with poor response to immune checkpoint inhibitors (ICI). However, most studies have focused on patients with traditional actionable oncogenes (e.g., EGFR, ALK, ROS1, RET), leaving it unclear whether additional biomarkers can aid in treatment stratification for this population.

Methods: Clinicopathologic and outcome data were collected from patients with metastatic, oncogene driver-negative, NSCLC who received ICI across nine academic cancer centers in US and EU.

Targeted exome sequencing was performed to identify genomic correlates of response to ICI. Tumor-infiltrating lymphocytes (TILs) densities were calculated from H&E slides using machine learning.

Results: Among 6,005 patients with metastatic NSCLC analyzed, 741 (12.4%) had never used tobacco and tested negative for actionable oncogenes. Median age was 64 years, 59.8% were women, 88.2% had ECOG PS 0/1, and 83.8% had adenocarcinoma. At a median follow-up of 38.0 months, objective response rate (ORR) was 22.3%, median progression-free survival (mPFS) and overall survival (mOS) were 4.5 and 16.8 months. Patients with PD-L1 TPS ≥1% had significantly higher ORR (32% vs. 17%, p<0.01), and longer mPFS (HR: 0.74, p<0.01) compared to those with PD-L1 <1%. Similarly, patients with very high TMB (≥90th percentile) had higher ORR (52.2% vs 22.9%, p<0.01), longer mPFS (HR 0.48, p<0.01), and mOS (HR 0.40, p<0.01) compared to those with a TMB<90th percentile. Patients with both PD-L1≥1% and TMB ≥90th percentile had the highest ORR (83.3%), longest mPFS (23.0 months, p<0.01), and mOS (not reached, p<0.01) compared to those with either biomarker alone (Figure 1A-C). Treatment outcomes also varied by regimen: patients receiving dual PD-(L)1+CTLA-4 blockade had the longest mPFS (9.4 vs. 6.8 vs. 2.9 months, p<0.01) and mOS (43.3 vs. 18.2 vs.14.8 months, p<0.01) compared to PD-(L)1+chemotherapy and PD-(L)1 monotherapy, respectively. Machine learning-based assessment of TILs showed significantly higher ORR and longer mPFS among patients with high versus low TILs density (Figure 1D-F). Gene mutation enrichment analysis identified mutations in TP53, KMT2D and NF1 among responders to ICI (Figure 1G), while whole transcriptome sequencing identified upregulation in MHCI/II antigen presentation, as well as increased signatures of T-cell activation and proliferation among responders to ICI (Figure 1H).

Conclusions: These results highlight how PD-L1≥1%, TMB≥90th percentile, an immune-enriched tumor microenvironment and dual-ICI regimens are associated with improved outcomes in patients with oncogene driver negative NSCLC without history of tobacco use, aiding personalized ICI use in this understudied population.

Introduction: Response rates to anti-programmed cell death 1 therapy (anti-PD-1) in metastatic non-small cell lung cancer (mNSCLC) patients with PD-L1 low or negative tumors are generally low. To overcome resistance to anti-PD-1, we combined ipilimumab, nivolumab and medium dose radiotherapy (IPI-NIVO and mRT). Here, we evaluated the safety and efficacy of IPI-NIVO and mRT in mNSCLC patients that progressed on prior anti-PD-1 therapy.

Methods: This single-arm, prospective phase II trial aimed to enroll 30 evaluable patients, with low (1-49%) and negative (<1%) tumor PD-L1 expression. Primary endpoints were safety, disease control rate (DCR) and objective response rate (ORR), measured on non-irradiated tumor lesions. Treatment consisted of IPI 1mg/kg Q6W and NIVO 240mg Q2W for 6 weeks together with mRT, delivered as 3x8Gy to max 4 lesions. Next, IPI 1mg/kg Q6W and NIVO 360mg Q3W was given until disease progression, unacceptable toxicity or 2 years of treatment completion.

Results: In the intention-to-treat population, 31 patients were included. ORR and DCR was achieved in 9/31 (29%) and 18/31 patients (58%). Baseline sum of longest diameters (bSLD) based on RECIST, along with blood inflammatory markers and albumin levels, were predictive of treatment response. Median follow-up was 10.5 months, with significant differences in overall survival (OS) between patients with progressive disease, stable disease and partial/complete response as best achieved response (median OS 3.1 vs 13.5 vs 22.5 months, HR 0.158 and HR 0.062, p<0.001). All patients experienced treatment-related AEs; grade 3 was the highest, observed in 8/31 patients (26%).

Conclusions: Our study showed an ORR in 29% to IPI-NIVO and mRT in mNSCLC patients with low and negative tumor PD-L1 expression, progressing after first-line anti-PD1 therapy. ORR was associated with improved OS. The study treatment was safe and tolerable. bSLD, inflammatory blood markers and albumin levels may serve as predictive marker for treatment response.

PT2.11.03 Phase I Study of Trametinib, Anlotinib, and Tislelizumab in KRAS-Mutant NSCLC: Safety, RP2D, and Preliminary Efficacy

B. Han, J. Lu, H. Zhong, T. Chu, Y. Lou, R. Zhong, W. Zhang, C. Shi, X. Zhang, L. Xiong, Z. Gao, J. Qian, J. Teng
Shanghai Chest Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai/CN

Introduction: The treatment of KRAS-mutant NSCLC in the later-line setting remains a challenge in clinical practice. Our previous clinical study (NCT04967079) found that the combination of trametinib and anlotinib demonstrated promising clinical efficacy in the later-line treatment of non-G12C KRAS-mutant NSCLC patients. Translational research revealed that anlotinib combined with trametinib could enhance PD-L1 expression and NK cell infiltration. However, the safety and efficacy of the triple therapy with trametinib, anlotinib, and tislelizumab in second-line or later-line treatment for KRAS-mutant NSCLC remain unclear, particularly in patients who have previously received immunotherapy.

Methods: This phase I clinical trial (NCT06456138) enrolled patients with advanced KRAS-mutant NSCLC patients who had previously received at least one standard therapy from June 7, 2024, to December 24, 2024. Patients underwent a trametinib and anlotinib crossover ramp-up trial based on the "3+3" dose-escalation design. Dosage A: 1 mg trametinib plus 6 mg anlotinib; Dosage B: 1 mg trametinib plus 8 mg anlotinib; Dosage C: 2 mg trametinib plus 6 mg anlotinib; Dosage D: 2 mg trametinib plus 8 mg anlotinib. Trametinib and anlotinib were orally administered once daily, with anlotinib given every two weeks followed by a one-week discontinuation cycle. After 2 cycles of trametinib plus anlotinib therapy, the combination of trametinib, anlotinib, and tislelizumab (200 mg, Q3W) was introduced starting from the third cycle. The primary endpoint was to evaluate the safety profile and determine the recommended phase 2 dose (RP2D). Secondary endpoints included progression-free survival (PFS), overall survival (OS), and objective response rate (ORR).

Results: A total of 12 patients with KRAS-mutant NSCLC were enrolled, including 3 with KRAS G12C mutations, 5 with KRAS G12D mutations, 3 with KRAS G12V mutations, and 1 with a KRAS G12R mutation. The majority of patients (10 out of 12) were male, and half had a history of smoking. Eight patients had received first-line standard therapy, while four had undergone third-line treatment. As of the data cutoff date (March 7, 2025), drug-related adverse events (AEs) were observed across different dosage groups. In Group A, reported AEs included rash (Grade 1, Grade 2), diarrhea (Grade 1, Grade 2), hypertension (Grade 1), bleeding (Grade 3), pneumonia (Grade 2), and increased creatine kinase (Grade 2). Group B experienced rash (Grade 1), diarrhea (Grade 1, Grade 2), and hypertension (Grade 1). In Group C, AEs included rash (Grade 1), diarrhea (Grade 1, Grade 2), nausea (Grade 1), oral mucositis (Grade 1), and decreased body weight (Grade 1). Group D reported rash (Grade 1, Grade 2), diarrhea (Grade 1, Grade 2), hypertension (Grade 3), pneumonia (Grade 2), facial swelling (Grade 1), and increased creatine kinase (Grade 1). The median PFS for all 12 patients was 171 days, while the median OS was not reached. The ORR was 33.3%.

Conclusions: These findings suggest that the RP2D for future trial is 2 mg trametinib + 8 mg anlotinib + tislelizumab (200 mg, Q3W). This study provides a potential therapeutic strategy for refractory KRAS-mutant NSCLC patients (especially the patients who have previously received immunotherapy).

PT2.11.04 Divergent Mechanisms of Hyper-Progressive Disease in Non-Small Cell Lung Cancer Treated With Immune Checkpoint Inhibitors

S. Shim[1,2], D.Y. Jeong[1], Y.J. Oh[2], H. Kim[1], J. Kim[1], S. Park[1], H.A. Jung[1], J-M. Sun[1], J.S. Ahn[1], M-J. Ahn[1], H.Y. Lee[1,2], S-H. Lee[1,2]
[1]Samsung Medical Center, Seoul/KR ,[2]Sungkyunkwan University, Seoul/KR

Introduction: Hyper-progressive disease (HPD) has emerged as an atypical response pattern to immune checkpoint inhibitors (ICIs), characterized by accelerated tumor progression and profoundly unfavorable clinical outcomes. Although its underlying mechanisms remain unclear, emerging evidence implicates both tumor-intrinsic properties and immune-mediated processes in its development. Lung adenocarcinoma (LUAD) and lung squamous cell carcinoma (LUSC), the two major histological subtypes of non-small cell lung cancer (NSCLC), exhibit fundamentally distinct tumor biology and immune microenvironments. This study aims to delineate the clinical and molecular characteristics of HPD across tumor subtypes to improve patient stratification and optimize the application of ICIs.

Methods: We retrospectively analyzed 630 patients with advanced NSCLC who received ICI monotherapy. Among them, 318 patients who exhibited progressive disease (PD) according to RECIST 1.1 were further classified into HPD and non-HPD based on volumetric assessment. Patients with PD who did not meet the volumetric criteria for HPD were defined as non-HPD. Subsequent analyses were conducted to evaluate clinical and molecular landscapes between these two groups. Transcriptomic profiling of pre-treatment tumor specimens was performed to investigate subtype-specific features of HPD, including gene set enrichment, cytokine signaling inference, and immune cell deconvolution. Systemic immune alterations were assessed using multiparametric flow cytometry on paired peripheral blood samples collected before and during treatment.

Results: HPD occurred in 10.2% of patients (N = 64; LUAD 9.8%, LUSC 11.1%) and was associated with significantly inferior overall survival compared to non-HPD (median OS, 4.6 vs 8.7 months; hazard ratio [HR] = 2.05; 95% CI, 1.55-2.71; P < 0.0001). In LUAD HPD, transcriptomic analysis revealed a marked upregulation of granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling (P = 0.01), accompanied by increased M2-like macrophages (P < 0.001) and macrophage/dendritic cell trafficking signatures (P = 0.01). Peripheral immune profiling further demonstrated an expansion of circulating myeloid populations following ICI treatment. Collectively, these findings suggest that HPD in LUAD may be driven by a pronounced shift toward an immunosuppressive phenotype. In contrast, LUSC did not exhibit HPD-specific transcriptional or systemic immune changes. A pervasive immunosuppressive tumor microenvironment (TME) was observed in LUSC non-HPD, characterized by enrichment of M2-like macrophages (P = 0.01), angiogenic signatures (P = 0.002), and epithelial-mesenchymal transition (EMT) pathways (P = 0.003). However, these features were not significantly observed in LUSC HPD, suggesting that its development in this subtype may involve alternative mechanisms, potentially driven by tumor-intrinsic programs. The presence of immunosuppressive traits in LUSC may obscure the distinction of HPD within this subtype, whereas aberrant immune perturbations may serve as key determinants of HPD development in LUAD.

Conclusions: HPD in advanced NSCLC may arise through divergent biological mechanisms shaped by histological subtypes. In LUAD, HPD may appear to be associated with immunosuppressive remodeling, while in LUSC, it is more likely governed by tumor-intrinsic pathways independent of immune modulation. These findings highlight the clinical relevance of histology-specific molecular stratification for identifying patients at heightened risk of HPD and underscore the importance of tailoring immunotherapeutic strategies to each tumor subtype.

PT2.11.05 IFI6-High Cancer-Associated Fibroblasts Impede Immunotherapy Response in NSCLC

L. Lin, Z. Dong, Y. Zhang
Nanfang Hospital, Southern Medical University, Guangzhou/CN

Introduction: Despite groundbreaking advances with immune checkpoint inhibitors (ICIs) in non-small-cell lung cancer (NSCLC), the objective response rate (ORR) to ICI remains suboptimal. Key impediments to ICI response involve tumor microenvironment (TME) immunosuppression requiring further elucidation.

Methods: Paired pre- and post-neoadjuvant chemoimmunotherapy tumor specimens from seven NSCLC patients were subjected to single-cell RNA sequencing (scRNA-seq) to delineate dynamic TME remodeling. The transcriptomic atlas stratified by pathologic response was used to identify the pivotal cell subset and unveil its key molecular signatures, with validation through clinical cohorts and in vitro/in vivo functional assays. CellChat analysis was applied to further decoded the downstream target cell network.

Results: Integrative scRNA-seq analysis revealed non-major pathologic response (NMPR) patients had expanded immunosuppressive CAFs and depleted cytotoxic GZMB+CD8+ T/NK cells versus major pathologic response (MPR) patients. Augur algorithm prioritized CAFs as the top discriminative subset, validated by NMPR_CAF signature predicting successfully in external cohorts. Further screening by Friends algorithm revealed IFI6 as the key hub gene. Confirming in clinical samples of NMPR patients, IFI6 was consistently elevated. Notably, IFI6-knockdown in CAFs (CAFshIFI6) co-injected with LLC1 tumors inhibited tumor growth in NSG mice and diminished ICI resistance in a CDX model, indicating that IFI6-high CAFs have direct interaction with tumor cells and influence ICI efficacy. Clinically, patients with IFI6-high CAFs showed inferior survival post-immunotherapy. Mechanistically, IFI6+ CAFs exhibited crosstalk with lipid-associated macrophages and cholesterol metabolic reprogramming.

Conclusions: High baseline IFI6 expression in CAFs fosters the immunosuppressive TME formation through dual interactions with tumor cells and lipid-associated macrophages, compromising ICI efficacy in NSCLC. Targeting IFI6 synergizes with ICIs may overcome primary resistance.

PT2.12.01 Osimertinib Combined With Tegavivint Is Safe and Tolerable as First-Line Therapy in Patients With Metastatic EGFR-Mutated NSCLC

R. Memmott[1], J. Gheeya[1], L. Wei[1], N.L. Abbott[1], K.L. Hill[1], J.Y. Na[1], M.A. Phelps[1], W. Yang[1], D. Stenehjem[2], S.K. Horrigan[3], A. Duncan[3], D. Brown[1], G.A. Otterson[1], J. Kaufman[1], A. Alahmadi[1], M. Li[1], K. He[1], C.J. Presley[1], D.H. Owen[1], D.P. Carbone[1]
[1]The Ohio State University Comprehensive Cancer Center--James, Columbus/OH/USA ,[2]University of Minnesota, Minneapolis/MN/USA ,[3]Iterion Therapeutics, Houston/TX/USA

Introduction: Epidermal Growth Factor Receptor (EGFR) tyrosine kinase inhibitors (TKIs) improve clinical outcomes for patients with EGFR-mutated non-small cell lung cancer (NSCLC). However, EGFR TKIs are not curative even when combined with other therapies because of drug-tolerant persister (DTP) cells. Our preclinical studies showed that a subset of EGFR-mutated lung cancer cells enter a persistent state in response to TKIs due to increased transcriptional activity of β-catenin. Treatment of mice bearing EGFR-mutated NSCLC xenografts with the combination of an EGFR TKI and a β-catenin inhibitor caused a greater depth and duration of response than treatment with an EGFR TKI alone. We also observed that patients with EGFR-mutated NSCLC who had the greatest increase in serum levels of the secreted β-catenin transcriptional target PAI-1 following treatment with a TKI had significantly worse progression free survival. These observations provided rationale for a clinical trial that evaluates the combination of an EGFR TKI with an inhibitor of β-catenin transcriptional activity. Tegavivint inhibits the transcriptional activity of β-catenin by disrupting its interaction with its binding partner TBL1 and has been evaluated as a single agent for the treatment of both desmoid tumors and hepatocellular carcinoma.

Methods: NCT04780568 is a single-arm phase Ib clinical trial that investigated the EGFR TKI osimertinib in combination with escalating doses of tegavivint. Patients with metastatic EGFR-mutated NSCLC who had not received prior treatment with an EGFR TKI were eligible. All participants received the FDA-approved dose of osimertinib, and tegavivint was administered using a dose escalation schedule with four dose levels. Dose escalation was determined by Bayesian optimal interval design. The combination of osimertinib and tegavivint was given for four 28-day cycles. Patients then continued maintenance treatment with osimertinib alone. The primary objectives were to assess the safety and tolerability of the combination and to determine the recommended phase 2 dose (RP2D) of tegavivint. Secondary objectives included objective response rate, median duration of response, progression free survival, and overall survival.

Results: Sixteen evaluable patients were treated on study with three patients at each of the first three dose levels, and seven patients at the highest dose level of tegavivint (8 mg/kg), which was determined to be the recommended phase 2 dose. No dose limiting toxicities nor treatment-related serious adverse events occurred. The most common grade 1-3 adverse events included hematologic and GI toxicities, which were likely attributable to osimertinib. Pharmacokinetic analysis showed a dose-dependent increase in the Cmax and AUC of tegavivint, and plasma levels of osimertinib were comparable to those seen historically when administered as a single agent. Clinical outcome data is maturing.

Conclusions: This phase Ib trial demonstrated that the combination of osimertinib and tegavivint is safe and tolerable as first-line therapy in patients with metastatic EGFR-mutated NSCLC. This novel combination has the potential to improve the durability of response through targeting DTP cells and may be better tolerated than current FDA-approved combinations that use chemotherapy or antibody-based therapies. These data provide support for a phase 2 head-to-head study comparing the efficacy of osimertinib versus osimertinib plus tegavivint.

PT2.12.02 Effect of JIN-A02, a Novel 4Th-Generation EGFR-TKI, on Multiple EGFR Mutations in Comparison With 3Rd-Generation EGFR-TKIs

S-M. Lim[1], B.S. Kim[2], W. Yu[2], S-K. Choi[2], A. Jo[3], E. Seah[3], C. Kim[3], S. Han[3], B.C. Cho[4], H-Y. Kim[5]
[1]Yonsei Cancer Center, Yonsei University College of Medicine, Seoul/KP ,[2]Daegu Gyeongbuk Institute of Science & Technology (DGIST), Daegu/KR ,[3]J INTS BIO Inc., Seoul/KR ,[4]Yonsei Cancer Center, Yonsei University College of Medicine, Seoul/KR ,[5]Core Protein Resources Center, Daegu-Gyeongbuk Institute of Science and Technology (DGIST), Daegu/KR

Introduction: JIN-A02, a novel fourth-generation tyrosine kinase inhibitor (TKI) targeting the epidermal growth factor receptor (EGFR) C797S mutation, is currently undergoing phase 1/2 clinical trials in patients with EGFR-mutated non-small cell lung cancer (NSCLC) in Korea, the USA, and Thailand (NCT05394831). NSCLC patients harboring acquired EGFR C797S mutations often exhibit co-occurring mutations, such as exon 19 deletions or T790M, as a result of targeted therapies, leading to tumor tissue heterogeneity. This heterogeneity significantly limits therapeutic options for these patients. To address this challenge, there is an unmet need for the development of fourth-generation EGFR-TKIs capable of targeting multiple EGFR mutations and effectively suppressing heterogeneous tumor tissues. With a view to evaluating the activity of JIN-A02 against common EGFR mutations (including T790M), we conducted an in silico study to estimate its binding affinity compared with third-generation EGFR-TKIs along with an in vitro study to calculate its inhibitory concentration (IC90) in EGFR-mutated cell lines.

Methods: Docking simulation of ATP, JIN-A02, osimertinib and lazertinib were performed using Autodock Vina with the T790M/L858R (pdb: 5EM7) and the T790M/L858R/C797S(pdb: 6LUD) protein structures. Cell-based assays were conducted to determine the IC90 values of JIN-A02 and Osimertinib. EGFR mutant cell lines were cultured and treated with various concentrations of each compound. The cell viability was assessed using an MTT assay, and the concentration required to IC90 of cell growth was calculated.

Results: In the in silico study, the docking score of JIN-A02 for EGFR L858R/T790M dual mutations was -9.043. Given the docking score of ATP for the same mutations (-6.849), JIN-A02 showed better binding affinity. For EGFR L858R/T790M/C797S triple mutation, the docking scores were as follows: JIN-A02 (-9.732), osimertinib (-6.816), lazertinib (-7.846), and ATP (-7.638). In the in vitro study, the IC90 value of JIN-A02 was 229 ng/mL, while osimertinib was >1000 ng/mL in an EGFR ex19del mutant cell line. Similarly, the IC90 value of JIN-A02 was 501 ng/mL, whereas that of osimertinib was >1000 ng/mL in an EGFR L858R mutant cell line.

Conclusions: We demonstrated that JIN-A02 exhibited potent binding affinity to the ATP-binding site of EGFR harboring double and triple mutations, surpassing the binding affinities of third-generation EGFR-TKIs, such as osimertinib and lazertinib. In line with this enhanced binding affinity, the in vitro study showed significantly lower IC90 value, effectively suppressing the proliferation of EGFR-mutated cell lines. These findings suggest that JIN-A02 has the potential to address the unmet therapeutic needs for NSCLC patients with heterogeneous EGFR mutations and, hence, may be a promising option for overcoming tumor tissue heterogeneity.

Introduction: Given the high incidence of brain metastases (BMs) in patients with HER2-mutant NSCLC, it is important to consider the intracranial activity of emerging HER2-targeting therapies; however, patients with active BMs at baseline are often excluded from clinical trials. Zongertinib is an irreversible tyrosine kinase inhibitor that selectively inhibits HER2 while sparing EGFR, thereby limiting associated toxicities. Phase Ib of Beamion LUNG-1 (NCT04886804) is evaluating zongertinib in patients with HER2-mutant advanced/metastatic NSCLC, including those with BMs at baseline. In an earlier analysis of previously treated patients with HER2-mutant NSCLC, zongertinib demonstrated durable clinical benefit with a manageable safety profile. Here, we report data from previously treated patients with active BMs (Cohort 4) or stable/asymptomatic BMs (Cohort 1) at baseline.

Methods: In Cohort 1, patients were initially randomized to receive zongertinib 120 mg or 240 mg once-daily; the 120 mg dose was selected at an interim analysis. Once selected, all new patients in all cohorts received zongertinib 120 mg. The primary endpoint in Cohort 1 was objective response (RECIST v1.1) by blinded independent central review (BICR). Secondary endpoints included duration of response (DoR) and intracranial objective response (RANO-BM) for patients with baseline central nervous system (CNS) lesions. In Cohort 4, the primary endpoint was intracranial objective response according to RANO-BM by BICR. Secondary endpoints included DoR and progression-free survival according to RANO-BM by BICR (CNS lesions).

Results: As of November 29, 2024, 75 patients had received zongertinib 120 mg in Cohort 1. In the 28 patients with stable/asymptomatic BMs at baseline, the confirmed systemic objective response rate (ORR) was 64% (95% CI: 46-79) and DoR was 14.1 months (95% CI: 4.2-14.1). In 47 patients without BMs, the confirmed systemic ORR was 74% (95% CI: 61-85); DoR was not yet mature. Overall, 27 patients were RANO-BM eligible; the confirmed intracranial ORR was 41% (95% CI: 25-59), including 4 (15%) patients with an intracranial complete response. The intracranial disease control rate was 81% (95% CI: 63-92). Of the 18 RANO-BM eligible patients who had not received brain radiotherapy prior to treatment, 2 had a complete response (CR) and 3 had a partial response (PR). Of the 9 RANO-BM eligible patients who had received brain radiotherapy prior to treatment, 2 patients had a CR and 4 had a PR. Treatment-related adverse events (all/grade ≥3) were reported in 100%/21% of patients with BMs and 96%/15% of patients without BMs. First data from previously treated patients with active BMs (Cohort 4) and updated data for those with stable/asymptomatic BMs (Cohort 1) will be available in May 2025. At the meeting, we plan to present intracranial response by RANO-BM and RECIST v1.1, and PRO data (disease-related symptom and physical functioning scores) for patients with active BMs, and intracranial response by RECIST v1.1 for those with stable/asymptomatic BMs.

Conclusions: Zongertinib demonstrated systemic and intracranial efficacy with a manageable safety profile in patients with advanced/metastatic HER2-mutant NSCLC and BMs at baseline.

Introduction: In the Phase II SAVANNAH study (NCT03778229), treatment with osimertinib (an oral EGFR-TKI) + savolitinib (an oral, highly selective MET-TKI) showed high, clinically meaningful and durable responses in patients with EGFRm advanced NSCLC with high levels of MET overexpression and/or amplification after progressive disease (PD) on osimertinib. We report patient-reported outcomes (PROs) from SAVANNAH in the primary efficacy population.

Methods: Patients in the primary efficacy population (N=80) had EGFRm advanced NSCLC with MET overexpression (MET IHC3+/≥90% [3+ intensity in ≥90% of tumour cells]) and/or amplification (FISH10+ [≥10 MET gene copies]) after PD on 1L osimertinib, and received osimertinib 80 mg QD + savolitinib 300 mg BID. HRQoL, function and symptoms were measured using EORTC QLQC30/LC13 questionnaires; impact of treatment/disease on health state was measured using EQ-5D-5L; tolerability was assessed using PRO-CTCAE (Table). Data reported from baseline (BL) up to C8D1. DCO: 23 Aug 2024.

Results: EORTC QLQ-C30/-LC13 compliance rates were moderate to high (80% at BL, between 56-70% across visits up to C8D1). GHS showed a consistent, small improvement (3-7 points) across visits; ~30-50% of patients experienced a clinically meaningful improvement from BL; 30-50% remained stable. Approximately ≥70% of patients experienced improved or stable functional and symptom scores over time (EORTC QLQ-C30/-LC13). EORTC QLQ-C30 showed a trend of small improvements (0.4-7 points) across all functional scales, and clinically meaningful improvements in the symptoms of dyspnoea, insomnia and appetite loss; small improvements (3-7 points)/stable scores were observed for fatigue, pain, nausea/vomiting, constipation, diarrhoea and financial difficulties. EORTC QLQ-LC13 showed clinically meaningful improvement in cough and small improvements for dyspnoea, haemoptysis, dysphagia and pain in chest. Symptom improvement rates were high across EORTC QLQ-C30/LC13; EORTC QLQ-LC13: haemoptysis (75%), pain in chest (83%). TTD varied across symptom scores; median TTD ranges were 5.52-13.90 months (EORTC QLQ-C30) and 2.79 months-NR (EORTC QLQ-LC13). EQ-5D-5L showed small improvements in mean VAS scores and index scores (64.8 to 66.2 and 0.68 to 0.72-0.77 at BL [n=64] and C8D1/across visits [n=30], respectively). PRO-CTCAE results showed that osimertinib + savolitinib was generally well-tolerated across visits.

Conclusions: In SAVANNAH, osimertinib + savolitinib treatment led to improved or stable disease/treatment-related symptoms, functions and overall HRQoL, indicating a favourable impact on PROs in patients with EGFRm and MET-overexpressed and/or amplified advanced NSCLC with PD on 1L osimertinib. These data further support osimertinib + savolitinib as a new treatment option in this setting.

MONDAY, SEPTEMBER 8, 2025 - 14:15 - 15:00

PT2.13.01 A Phase II Trial of Induction Camrelizumab Plus Chemotherapy Followed by Chemoradiotherapy and Consolidation in Limited-Stage SCLC

D. Liu, M. Hu, L. Yang, J. Ni, Y. Xu
shanghai pulmonary hospital, Shanghai/CN

Introduction: Limited-stage small cell lung cancer (LS-SCLC) comprises 15-30% of SCLC cases, yet relapses occur frequently following definitive therapy. Although durvalumab consolidation has enhanced outcomes compared to traditional concurrent chemoradiotherapy (CRT), disease progression remains a formidable challenge. Building on findings in locally advanced non-small cell lung cancer, where induction immunotherapy plus chemotherapy improved survival, we conducted a Phase II randomized trial to evaluate whether a similar approach might benefit patients with LS-SCLC. This trial examined the efficacy and safety of induction camrelizumab plus chemotherapy, followed by CRT and camrelizumab consolidation.

Methods: This investigator-initiated, phase II, open-label, randomized controlled trial (ChiCTR2000032275) was conducted at Shanghai Pulmonary Hospital. Patients were randomly assigned (1:1) to either an experimental regimen of induction immunotherapy and chemotherapy (two cycles of camrelizumab plus etoposide-platinum [EP] or etoposide-carboplatin [EC]) followed by CRT, prophylactic cranial irradiation (PCI), and up to 12 months of camrelizumab consolidation (camrelizumab group), or a control regimen of induction chemotherapy (EP or EC) followed by CRT and PCI (cCRT group). The primary endpoint was the 1-year progression-free survival (PFS) rate. Secondary endpoints included overall survival (OS), objective response rate, and safety. Adverse events were assessed according to Common Terminology Criteria for Adverse Events (CTCAE) version 5.0. Kaplan-Meier estimations, stratified log-rank tests, and Cox proportional-hazards models were employed to compare survival outcomes.

Results: Between November 2020 and March 2024, 65 patients were screened for eligibility, and 41 were randomly assigned to receive either camrelizumab (n=21) or standard cCRT (n=20). The median follow-up time was 20.9 months (95% CI: 18.6-23.2 months) for the camrelizumab group and 23.2 months (95% CI: 16.3-30.2 months) for the cCRT group. All patients treated with camrelizumab achieved a partial response, compared with 84.2% in the cCRT arm. The 1-year PFS rate was higher in the camrelizumab group than in the cCRT group [59.9% (95% CI: 34.6-85.2%) vs. 39.5% (95% CI: 15.6-63.4%)], and the median PFS was not reached in the camrelizumab arm, whereas it was 11.4 months (95% CI: 9.8-13.0 months) in the cCRT arm (HR 0.42, 95% CI: 0.18-0.96, p=0.047). Similarly, the median OS was not reached in the camrelizumab group, compared with 23.9 months (95% CI: 15.3-32.5) in the cCRT group (HR 0.32, 95% CI: 0.11-0.96, p=0.044). The 1-year OS rate was 100% for camrelizumab and 89.2% for cCRT. Subgroup analysis further indicated that an absolute lymphocyte count (ALC) >2.0 × 10^9/L correlated with significantly longer PFS in the camrelizumab arm. No immune-related deaths were reported; however, one patient experienced grade 3 reactive capillary endothelial proliferation. Notably, induction camrelizumab did not lead to an increased incidence of radiation pneumonitis.

Conclusions: These findings suggest that induction camrelizumab plus chemotherapy followed by CRT and camrelizumab consolidation may improve both PFS and OS in LS-SCLC without exacerbating toxicity. Further research to refine treatment sequencing could provide vital improvements in managing this challenging disease.

PT2.13.02 Multi-Cycle Low-Dose Radiotherapy Reshapes Immunochemotherapy for ES-SCLC: The SPUR Phase II Trial

Z. Yao[1], W. Zhou[2], Z. Yang[3], Y. Zhang[4], S. Zhang[5], D. Sun[6], W. Zhao[7], Z. Lin[8], R. Tong[1], Y. Gong[1], Y. Lu[1]

Introduction: Despite immunotherapy incorporation into first-line treatment for extensive-stage small-cell lung cancer (ES-SCLC), its survival benefits remain modest. Previous studies suggest that low-dose radiotherapy (LDRT) could enhance anti-tumor immune responses and may prolong immunotherapy efficacy. However, the therapeutic potential of single-cycle single-site LDRT remains suboptimal. We initiated a proof-of-concept trial to evaluate the feasibility, safety, and preliminary efficacy of adaptive multi-cycle LDRT combined with serplulimab-based immunochemotherapy in previously untreated ES-SCLC patients.

Methods: The SPUR trial (NCT05765825) is a multicenter, single-arm, phase II study enrolling treatment-naïve ES-SCLC patients. Participants receive four cycles of platinum-etoposide chemotherapy (cisplatin/carboplatin + etoposide) plus serplulimab, along with adaptive multi-cycle LDRT, followed by serplulimab maintenance. The LDRT protocol is as follows: (1) All patients receive LDRT at 15 Gy/5 fractions (15 Gy/5 f) concurrently in the first induction cycle. (2) If primary intrathoracic lesions exhibit <80% reduction or non-response by the end of second cycle, an additional 15 Gy/5 f LDRT is administered at third cycle. (3) For residual extrathoracic metastases, a final course of 15 Gy/5 f LDRT is delivered at cycle four. The primary endpoint is progression-free survival (PFS) per RECIST v1.1. Secondary endpoints include duration of response (DoR), disease control rate (DCR), overall survival (OS), and safety. Additionally, exploratory biomarkers include T-cell receptor (TCR) repertoire profiling and plasma extracellular vesicle proteomics.

Results: Sixty-one patients from 8 centers across China (median age, 60 years) were enrolled. 19 patients (31.1%) had liver metastases, and 10 patients (16.4%) had brain metastases. 13 patients completed all three LDRT cycles. At data cut-off (February 28, 2025), the median follow-up was 12.5 months (range: 0.8 - 21.9). The median PFS was 8.6 months (95% CI: 6.5 - 15.0), with 6-month PFS rate of 63.9% (95% CI: 53.0 - 77.2%) and 12-month PFS rate of 33.3% (95% CI: 21.8 - 50.8%). Patients without liver metastases (median PFS: 11.2 vs. 4.4 months; log-rank P = 0.002) experienced significantly longer PFS than those with liver metastases. The confirmed objective response rate (ORR) was 84.8% (50/59; 95% CI: 73.0 - 92.8%), and DCR was 88.1% (52/59; 95% CI: 77.1 - 95.1%). The median DoR was 8.2 months (95% CI: 4.1 - NR). The OS data was not mature yet. The incidence of any grade treatment-related adverse events (TRAEs) was 88.5% (54/61), and 39.3% (24/61) reported grade ≥ 3 TRAEs. Hematological toxicities were the most common TRAEs. Radiation-related toxicities were manageable, with 6 patients having grade 1/2 radiation pneumonitis; 4 patients reported grade 2 immune-related pneumonia. TCR-α/β-chain sequencing revealed that prolonged PFS was associated with increased TCR repertoire diversity after Cycle 1 but increased clonal TCR repertoires after Cycle 4. The proteomics of plasma extracellular vesicle showed patients with higher baseline expression of adaptive immune response pathway, or increased cytoplasm protein levels after cycle 4, had longer PFS.

Conclusions: This study demonstrated a promising survival benefit and manageable toxicity of first-line serplulimab and chemotherapy combined with multi-cycle LDRT in ES-SCLC. Sixteen patients (26.2%) are still on treatment, long-term follow-up and exploratory analysis results are warranted.

PT2.13.03 Spatial Multiomics Profiling Reveals Distinct Tumor Microenvironment and Therapeutic Targets in EGFR-Mutant NSCLC Transformed to SCLC

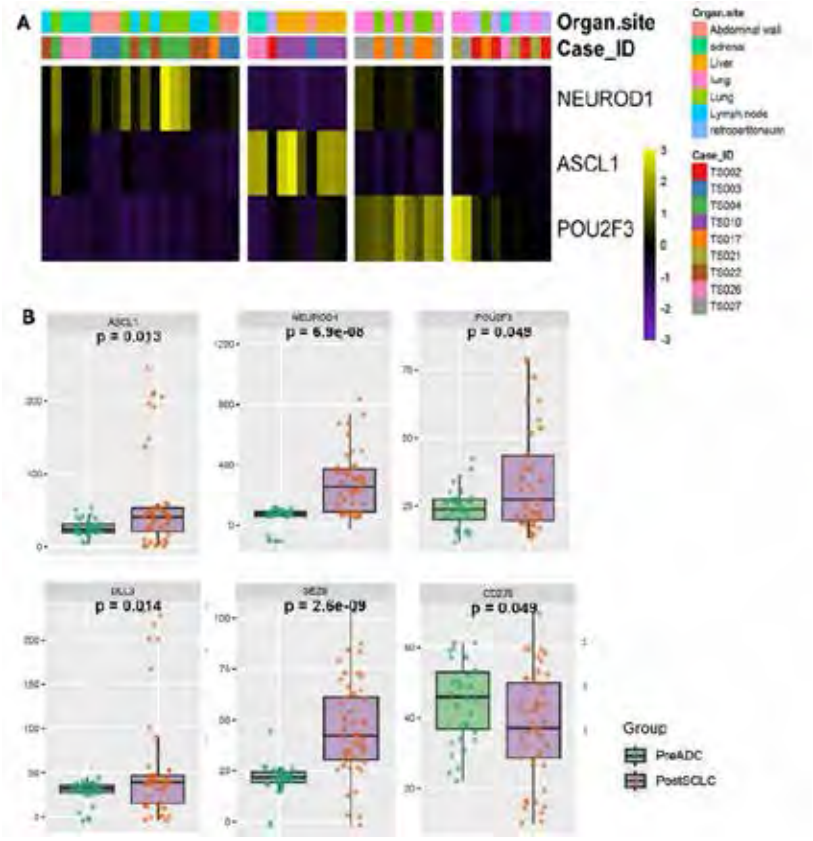
B. Zhang, H. Chen, A. Serrano, S. Hernandez, W. Lu, S. Trevino, N. Vokes, X. Liu, Y. Tian, N.O. Lermi, B. Zhu, A.C. Stewart, R.J. Cardnell, M.B. Nilsson, J.V. Heymach, J. Zhang, L. Solis soto, C.M. Gay, L. Byers, X. Le
University of Texas MD Anderson Cancer Center, HOUSTON/TX/USA

Introduction: 3-10% patients with EGFR-mutant non-small cell lung cancer (NSCLC) undergo histologic transformation to small cell lung cancer (SCLC) under therapeutic pressure. Previous studies identified genomic and transcriptomic characteristics accompanied with this transformation, however spatially resolved profiling of tumor microenvironment (TME) and molecular features of this transformation is lacking. In this study, we investigated spatial transcriptomics and proteomic profiling in pre-transformed EGFR NSCLC (pre-NSCLC) and post-transformed mixed-histology tumors/SCLC (post-mixed/post-SCLC) to shed light on the therapeutic vulnerabilities of this aggressive tumor plasticity.

Methods: Nanostring GeoMx® Digital Spatial Profiling (DSP) was used to analyze Whole Transcriptome Atlas (WTA, >18,000 genes) and 70 protein biomarkers in FFPE samples from patients (N=14) with EGFR NSCLC transformed to SCLC. Three patients have paired pre-NSCLC and post-mixed samples, including one patient with three longitudinal samples. Up to 12 regions of interest (ROIs) per sample were selected by expert pathologists and segmented into Tumor and TME compartments based on the expression of morphology markers (pan-CK, synaptophysin, and CD45). A total of 132 ROIs for WTA and 125 ROIs for protein analyses passed quality control filtering and were included in analyses. In addition, we performed in silico deconvolution of the gene expression data to estimate the abundance of cell populations of the TME.

Results: WTA analyses revealed all four molecular subtypes of SCLC in transformed cases with intra-tumoral heterogeneity. Interestingly, higher expressions of POU2F3 and NEUROD1 are seen across ROIs in the samples (Fig.1A). A subset of the tumor samples expressed higher DLL3, SEZ6 in post-SCLC; while CD276 was expressed across pre-/post-samples (Fig.1B), all are promising cell surface targets with therapeutics available in clinical setting. Gene Ontology (GO) enrichment analyses showed upregulation of neuronal developmental pathways and down regulation of antigen presentation, immune activation and angiogenesis when comparing post-mixed to pre-NSCLC. Lower percentages of macrophages, neutrophils and myeloid dendritic cells are seen in the TME of post-transformed SCLC (p<.0001). Proteomics analyses showed higher levels of immune checkpoints Tim-3, VISTA as well as immune cell markers CD3 and CD45 in pre-NSCLC compared to post-mixed.

Conclusions: These results highlight spatially resolved molecular and immune changes during EGFR-mutant NSCLC transformation to SCLC/mixed histology tumors. In addition, multiple cell-surface targets identified suggests targeted strategies such as antibody drug conjugates may be successful to treat this aggressive disease.



Keywords: SCLC, EGFR NSCLC transformation, spatial profiling

PT2.13 SMALL CELL LUNG CANCER AND NEUROENDOCRINE TUMORS

PT2.13.04 Real-World Multi-Institution Analysis of Patients With Small Cell Lung Cancer Treated With Tarlatamab

A. Cooper[1], J. Liang[2], S. McDonald[3], P. Clark[1], S. Saito[3], R. Daly[1], C.M. Rudin[1], J.F. Gainor[2], J. Sands[3], C.B. Meador[2]
[1]Memorial Sloan Kettering Cancer Center, New York/NY/USA ,[2]Massachusetts General Hospital Cancer Center, Boston/MA/USA ,[3]Dana-Farber Cancer Institute, Boston/MA/USA

Introduction: Tarlatamab, a DLL3 bispecific T-cell engager, was approved in relapsed small cell lung cancer (SCLC) based on the phase II registrational trial demonstrating responses in 32-40% of patients. Outcomes for patients receiving tarlatamab who would not have met eligibility criteria for trial inclusion have not been described.

Methods: We identified a cohort of patients with de novo SCLC who received at least one dose of tarlatamab between 5/16/2024 and 3/20/25 at three US academic institutions and analyzed clinical outcomes. Trial-ineligible population was defined as patients with ECOG performance status (PS)≥2, history of ≥grade 2 (G2) pneumonitis, untreated brain metastases, organ dysfunction, oxygen requirement or pleural effusion, history of stroke (past 12 months), or ejection fraction (EF)<50%.

Results: Seventy-five patients were included. Median age was 64 (range 24-82); 55% (n=41) were male and 89% (n=67) were white. Most patients (96%; n=72) were had former or current smoking history with median 40 pack-year exposure, and 61% (n=46) had extensive-stage disease at diagnosis. Tarlatamab was administered after median 9.6 months (range 0.1-45.2 months) with median 1 prior line of therapy after diagnosis of metastatic disease (range 0-6). Overall population: Median time on tarlatamab was 3.1 months, with 48% (n=36/75) continuing therapy at data cut-off. Most common reasons for discontinuation were progression or death (90%; n=35/39), followed by toxicity (10%; n=4/39). Sixty patients were evaluable for response. Best response by clinical assessment was complete or partial response (CR/PR) in 25% (n=15/60), stable disease (SD) or mixed in 25% (n=15/60), and progression in 50% (n=30/60). Seventeen percent (n=10/60) of evaluable patients received treatment beyond progression. Twenty-three percent (n=14/60) of evaluable patients had brain metastasis at progression on tarlatamab. Median overall survival was 8.1 months. Following the first two infusions, sixty percent of patients (n=45/75) experienced cytokine release syndrome (CRS; majority G1), and 32% (n=24/75) had immune effector cell associated neurotoxicity (ICANS; majority G2). Trial-ineligible population: Sixty-one percent of patients (n=46/75) would not have met trial inclusion criteria based on ECOG PS > 2 (20%; n=15/75), untreated brain metastases (24%; n=18/75), history of > G2 pneumonitis (12%; n=9/75), organ dysfunction (11%; n=8/75), pleural effusion or oxygen requirement (25%; n=19/75), EF <50% (16%; n=12/75), or stroke history (4%; n=3/75). Twenty-five patients (33%) met >1 exclusion criteria. In the trial-ineligible population, median time on tarlatamab was 2.4 months, with 46% (n=21/46) remaining on treatment at data cutoff. Tarlatamab was discontinued for progression/death in 88% (n=22/25) and for toxicity in 12% (n=3/25). Thirty-five patients were evaluable for response. Among evaluable patients, 20% (n=7/35) had CR/PR, 20% SD/mixed (n=7/35), and 60% PD (n=21/35). CRS occurred in 59% of patients (majority G2) and ICANS in 39% of patients (majority >G2).

Conclusions: Most patients in this cohort do not meet trial eligibility criteria, highlighting potential opportunity to treat a more broad population. These patients had comparable CRS rates but higher rates of ICANS, lower objective response rate, and more frequent primary progression. Detailed analyses are warranted to understand patient and disease characteristics predictive of toxicity and response to optimize patient selection.

PT2.14.01 SYSTEMS-2: A Randomised Phase II Study of Radiotherapy Dose Escalation in Pleural Mesothelioma

A. Chalmers[1], M. Ashton[2], L. Paterson[1], L. Alexander[1], J. Rice[1], C. Kelly[1], A. Shaw[1], L. Divers[1], E. Banks[1], K.N. Franks[3], I. Phillips[4], M. Ahmed[5], S. Sheridan[6], B. Laird[7]
[1]University of Glasgow, Glasgow/GB ,[2]Beatson West of Scotland Cancer Centre, Glasgow/GB ,[3]University of Leeds, Leeds/GB ,[4]Edinburgh Cancer Centre, Edinburgh/GB ,[5]Royal Marsden Hospital, London/GB ,[6]Queen Elizabeth University Hospital, Glasgow/GB ,[7]University of Edinburgh, Edinburgh/GB

Introduction: Malignant pleural mesothelioma (MPM) is an aggressive cancer in which pain is very common and analgesics often ineffective. Our SYSTEMS study demonstrated that palliative radiotherapy (20 Gray in 5 fractions) achieved significant pain improvement in one third of patients. We hypothesised that radiotherapy dose escalation would achieve pain relief in more patients and might improve radiological responses and survival.

Methods: SYSTEMS-2 was a randomised multicentre trial comparing hypofractionated, 'dose escalated' radiotherapy (36 Gy, 6 fractions, 2 weeks) with conventional 'control' radiotherapy (20 Gy, 5 fractions, 1 week). It was funded by June Hancock Mesothelioma Research Fund and Beatson Cancer Charity. Participants had a histological and/or multidisciplinary team diagnosis of MPM, Eastern Cooperative Oncology Group Performance Score 0-2, life expectancy >12 weeks and 'worst pain score' >4/10 after analgesia optimisation. Radiotherapy plans compatible with dose escalation were required prior to randomisation. Exclusion criteria included anti-cancer therapy within 4 weeks and previous radiotherapy to overlapping volumes. Primary endpoint was 'worst pain score' by Brief Pain Inventory (BPI) 5 weeks after start of radiotherapy. Secondary endpoints included acute toxicity, quality of life (QoL, weeks 5 and 9), radiological response (modified RECIST, week 9) and overall survival (OS). 112 patients were required to detect a 20% increase in proportion of responders with 90% power and 20% 1-sided statistical significance.

Results: 122 patients were consented between 2016 and 2022 of whom 110 were randomised (54 dose escalated, 56 control) across 17 sites. 'Worst pain' response rates in dose escalated and control groups were 42.6% and 35.7% respectively (intention to treat analysis). The difference of 6.9% was not statistically significant (80% confidential intervals (CI) 6.8-20.6%). Regarding secondary endpoints, toxicities were generally mild with modest increases in incidence of nausea (G1-2), pain (G2-3) and vomiting (G1) during treatment and radiation dermatitis (G1-2) after treatment in dose escalated patients. Pain (G1-2) was reported more frequently in control patients during follow-up. Median OS was 6.6 months (80% CI 4.8-7.5) in the dose escalated arm and 4.8 months (4.2-6.4) in the standard arm. The hazard ratio for death in the dose escalated arm was 0.65 (95% CI 0.44-0.97, p=0.035, Weibull analysis, Figure 1). Six-month OS rates were 51.9% (42.8-60.1) and 41.5% (32.8-50.0) in dose escalated and control arms respectively while 12-month OS rates were 27.4% (19.9-35.4) and 15.9% (9.98-22.3). There were no complete radiological responses (CR) but partial responses (PR) were observed in 18.5% of dose escalated and 10.7% of standard patients, with stable disease (SD) reported in 37.0% and 30.4% respectively. Clinical benefit rates (CR, PR and SD) were 56% and 41% in dose escalated and control arms, absolute difference of 15% (0.6-28.4). No difference in QoL parameters were observed at any timepoints.

Conclusions: SYSTEMS-2 demonstrated that both schedules were well tolerated. There was no improvement in the primary endpoint (worst pain score at 5 weeks) but a reducted risk of death was observed in patients receiving dose escalated radiotherapy and radiological data indicated higher clinical benefit in this group.

PT2.14.02 Human- and AI- Whole Slide Image Assessment of Tumor Immune Microenvironment of Pleural Mesothelioma in Prediction of Patients Outcome

G. Maggioni[1], F. Pezzuto[2], L. Brcic[3], L. Marsh[3], G. Ali[4], C. Romei[5], I. Strumfa[6], L. Carvalho[7], A.F. Ladeirinha[7], E. Faccioli[2], S. Zanella[2], A. Vilaia[8], L. Vedovelli[2], C. De Chellis[2], G. Pasello[2], F. Rea[2], F. Calabrese[2]
[1]Università degli Studi di Padova, 35121/IT ,[2]Università degli Studi di Padova, Padova/IT ,[3]Medizinische Universität Graz, Graz/AT ,[4]University of Pisa, Pisa/IT ,[5]Pisa University Hospital, Pisa/IT ,[6]Riga Stradins University, Riga/LV ,[7]University of Coimbra, Coimbra/PT ,[8]Carol Davila University of Medicine and Pharmacy, Bucharest/RO

Introduction: Tumor immune microenvironment (TIM) is critical in cancer progression and therapeutic response. Pleural mesothelioma (PM) shows limited efficacy of immune checkpoint inhibitors underscoring the need for reproducible TIM characterization to identify predictive biomarkers and improve stratification. No universally accepted method exists for a standardized evaluation of the TIM. This study aims to evaluate the concordance between human and AI- whole slide image (WSI) assessment for the quantification of TIM in PM samples, focusing on outcome prediction.

Methods: This preliminary report presents updated findings from the ANEMONE project (a multicenter prospective-retrospective study funded by the European Commission under the TRANSCAN initiative).Immunohistochemistry was performed for pivotal TIM markers. Human-WSI semi-quantitative evaluation was independently conducted by pathologists. AI-based WSI scoring was performed using dedicated software (Visiopharm®).Agreement between AI and human assessment was evaluated through Absolute Standardized Mean Differences (ASMD). Furthermore, Intraclass Correlation Coefficients (ICC) were calculated for continuous variables and Cohen's Kappa (weighted and unweighted) for categorical scores to explore both quantitative and ordinal agreement. Bland-Altman plots were used to visualize systematic bias and variability.A subset of 134 patient (96 males, 38 females; mean age 72years) with complete clinical follow-up was selected, of which 109 epithelioid and 25 sarcomatoid/biphasic mesothelioma. Prognostic significance of marker expression (both AI- and human-derived) was evaluated using Cox proportional hazards models, with hazard ratios (HR), p-values, and Harrell's C-index reported for each marker. Models for histological subtypes (epithelioid vs biphasic/sarcomatoid), were also evaluated and outcome was defined as vital status and time to event.

Results: ASMD analysis confirmed the presence of strong imbalance for CD20 across both score and percent measures (ASMD ≈ 0.66), indicating poor agreement between AI and human evaluation. CD4 and CD68 showed moderate differences (ASMD ≈ 0.19-0.25), while CD3, CD8, and CD163 displayed negligible ASMD values (< 0.1), suggesting high concordance between methods for these markersICC values confirmed excellent concordance for CD57 (ICC = 0.827) and good concordance for CD68 (ICC = 0.659), while CD8, CD3, CD4, CD20, and CD163 showed moderate agreement. Weighted Cohen's Kappa indicated substantial agreement for CD57 and CD68 (0.641 and 0.695), while CD20 had the lowest unweighted Kappa (0.237), reflecting poor categorical agreement. Bland-Altman plots for CD20 revealed a non-linear discordance pattern, with increasing underestimation by AI at intermediate and high expression levels.From a prognostic perspective, CD20 expression assessed by human scoring was significantly associated with improved survival in all cases (HR=0.944; $p < 0.01$) and in epithelioid mesotheliomas (HR = 0.95, p = 0.012). No such association was observed for AI-derived CD20 metrics. In contrast, CD8 expression assessed by AI correlated positively with reduced survival in all cases.

Conclusions: Our preliminary results suggest that AI can provide reliable support for specific markers such as CD8, CD57, and CD68. For some other biomarkers it cannot yet replace human eye, and a more in depth and extensive evaluation is mandatory to calibrate the AI algorithm to obtain reproducible results. Intriguingly CD20, particularly in the epitheloid mesotheliomas, could be a crucial prognostic parameter to assess.

PT2.14.03 Molecular Correlates of Response to Atezolizumab Plus Carboplatin and Paclitaxel in Patients With Thymic Carcinoma

Y. Shirai[1], T. Shukuya[1], T. Asao[1], Y. Goto[2], T. Mimori[1], K. Takayama[3], K. Kaira[4], H. Tanaka[5], R. Ko[6], Y. Amano[7], M. Tachihara[8], T. Suzuki[9], J. Tanizaki[10], S. Sugawara[11], Y. Zenke[12], M. Fujioka[1], T. Hayashi[1], K. Mori[6], K. Takahashi[1]
[1]Juntendo University Graduate School of Medicine, Tokyo/JP ,[2]National Cancer Center Hospital, Tokyo/JP ,[3]Kyoto Prefectural University of Medicine, Kyoto/JP ,[4]Saitama Medical University, Saitama/JP ,[5]Niigata Cancer Center Hospital, Niigata/JP ,[6]Shizuoka Cancer Center, Shizuoka/JP ,[7]Shimane University Faculty of Medicine, Shimane/JP ,[8]Kobe University Graduate School of Medicine, Hyogo/JP ,[9]Chiba University, Chiba/JP ,[10]Kindai University Faculty of Medicine, Osaka/JP ,[11]Sendai Kousei Hospital, Miyagi/JP ,[12]National Cancer Center Hospital East, Kashiwa/JP

Introduction: Despite the limited prognosis of advanced or recurrent thymic carcinoma (TC), the development and introduction of novel drugs is often delayed due to its rarity. We previously reported a multicenter, single-arm phase II study of atezolizumab with carboplatin plus paclitaxel in advanced or recurrent TC (Marble study, jRCT2031220144), showing an objective response rate (ORR) of 56%. In post-hoc analyses, PD-L1 expression (SP142) combining TC and IC measurements did not significantly correlate with ORR, but did correlate with longer progression-free survival. However, it is still unclear which patients benefit from this combination therapy. The purpose of this translational research is to characterize genomic and transcriptomic profile of TC and identify predictive response markers from results of Marble study.

Methods: Pretreatment formalin-fixed-paraffine-embedded (FFPE) samples were collected from advanced or recurrent TC patients participated in Marble study. We performed whole exome sequencing (WES) and RNA sequencing (RNA-seq). The analyses of somatic mutation, copy number variation, tumor mutational burden (TMB), and COSMIC mutation signature were conducted using WES data, and analyses of differential gene expression, clustering, and gene enrichment using RNA-seq data.

Results: Out of 48 patients enrolled in Marble study, FFPE samples from 34 patients were available for this biomarker study. 25 patients were responders (best overall response with complete response or partial response) and 9 patients were non-responders (best overall response with stable disease or progressive disease). Mutations in tumor suppressor genes such as CYLD (5/25 versus 0/9), TP53 (7/25 versus 0/9), and SLFN11 (5/25 versus 1/9) were abundant in responders compared with non-responders. Copy number analysis revealed deletions of MTAP, CDKN2A, and CDKN2B genes in 3 responders, but those alterations were not seen in non-responders. Median TMB for responders and non-responders were 10.7 mut/Mb and 12.3 mut/Mb, respectively. RNA-seq was performed to 30 samples which passed quality check, including 22 responders and 8 non-responders. The differential gene expression analysis revealed upregulation of immunoglobulin genes in responders. Gene ontology (GO) analysis to upregulated genes of responders showed enrichment in pathways such as “adaptive immune response based on somatic recombination of immune receptors built from immunoglobulin superfamily domains” and “leukocyte mediated immunity.”

Conclusions: In previously untreated advanced TC, high expression of PD-L1 in IHC, alterations in tumor suppressor genes, and upregulation of immune related pathways may be associated with beneficial response to atezolizumab plus carboplatin and paclitaxel. On the other hand, TMB did not correlate with treatment response.

PT2.14.04 Efficacy and Safety of Adebrelimab Plus Chemotherapy as Neoadjuvant Treatment for Unresectable Locally Advanced Thymic Carcinoma

N. XU[1], Z. Gao[1], C. Wang[1], F. Pan[1], Y. Shen[1], L. Zhu[1], J. Yuan[2], C. Zhao[2], Z. Gu[1], T. Mao[1], W. Fang[1]
[1]Shanghai Chest Hospital, Shanghai/CN ,[2]Jiangsu Hengrui Pharmaceuticals Co. Ltd., Shanghai/CN

Introduction: While surgery remains the gold standard for early-stage thymic carcinoma, complete resection proves challenging in locally advanced disease. Current multimodal approaches combining chemotherapy, surgery, and radiotherapy have shown limited efficacy in locally advanced cases. Given the unmet clinical need for this rare malignancy, we conducted this study to evaluate the efficacy and safety of adebrelimab combined with nab-paclitaxel and carboplatin as neoadjuvant therapy for unresectable locally advanced thymic carcinoma.

Methods: This study enrolled treatment-naïve patients (pts) with unresectable T3/T4NxM0 thymic carcinoma. Pts received neoadjuvant therapy with adebrelimab (20 mg/kg), nab-paclitaxel (260 mg/m^2), and carboplatin (AUC 4-5) every 3 weeks for ≤3 cycles, followed by surgical resection and adjuvant radiotherapy ± chemotherapy or definitive chemoradiotherapy. The primary endpoint was objective response rate (ORR). Secondary endpoints included surgical resection rate, R0 resection rate, major pathological response (MPR, ≤10% viable tumor cells), progression-free survival (PFS), overall survival (OS), and safety profile. Using a Simon two-stage design, if >2 of 9 initial pts achieved tumor response, enrollment would expand to 24 pts. Treatment efficacy would be considered positive if ≥10 pts achieved objective response.

Results: Between May 2023 and March 2025, 9 pts were enrolled in stage I, all completing planned neoadjuvant therapy. Four pts achieved objective response, while 5 had stable disease resulting in an ORR of 44.4% (4/9) and a DCR of 100% (9/9). Seven pts (77.8%, 7/9) proceeded to surgery, with 7 (100%, 7/7) achieving R0 resection at a median interval of 37 days (range: 30-40) post-neoadjuvant therapy. No treatment-related surgical delays or deaths were observed. Pathological evaluation demonstrated a pathological complete response rate of 14.3% (1/7) and an MPR rate of 42.9% (3/7). At the time of analysis, PFS and OS were not mature. The treatment demonstrated a favorable safety profile without surgical complications. Grade 3-4 adverse events occurred in 7 pts (77.8%), including neutropenia (55.6%, n=5), leukopenia (11.1%, n=1), and rash (11.1%, n=1). The immune-related adverse events (irAEs) associated with adebrelimab were mainly of grade 1-2 (55.6%, 5/9), including rash (22.2%, n=2), infusion reaction (11.1%, n=1), hepatic enzymes increased (11.1%, n=1). The incidence of grade 3 irAE was rash (11.1%, n=1).

Conclusions: In patients with unresectable locally advanced thymic carcinoma, neoadjuvant adebrelimab combined with chemotherapy demonstrated promising efficacy and an acceptable safety profile. The trial is still ongoing to complete accrual in stage II.

PT2.14.05 Redefining Clinical Outcomes for Peritoneal Mesothelioma (PeM) in the Era of Immunotherapy

A.H. Nassar[1], E. Bou Farhat[2], N. Ghandi[3], E. Adib[2], M. Rakaee[4], K. Raghav[5], D.J. Kwiatkowski[2], Y. Takabe[6]
[1]Yale Cancer Center, New Haven/CT/USA ,[2]Brigham and Women's Hospital, Boston/MA/USA ,[3]Caris Life Sciences, Irving/TX/USA ,[4]Oslo University Hospital, Oslo/NO ,[5]MD Anderson, Houston/TX/USA ,[6]Yale university, New Haven/MA/USA

Introduction: Therapeutic strategies for malignant PeM remain poorly defined, often borrowed from protocols developed for pleural mesothelioma (PM). Yet, in the era of immunotherapy, robust data on treatment outcomes specific to PeM are lacking, and direct comparisons to PM are virtually nonexistent—highlighting an urgent need for dedicated research and tailored therapeutic approaches.

Methods: 716 mesothelioma specimens with outcomes were molecularly profiled at Caris Life Sciences. A validation cohort of patients with PeM and PM was curated from Dana-Farber Cancer Institute (DFCI). Treatment groups included patients treated with immune checkpoint inhibitors (IO), primarily nivolumab and ipilimumab. Clinical endpoints included overall survival from the initiation of immunotherapy (IO-OS), and time to next treatment following immunotherapy (IO-TTNT). For the Caris cohort, IO-OS was derived from insurance claims data and calculated from the date treatment initiation (IO) to the date of last clinical contact. For the DFCI cohort, clinical outcomes were obtained through manual chart review and curation. Hazard ratio (HR) was calculated using the Cox proportional hazards model, and p values were calculated using the log-rank test. To characterize the tumor immune microenvironment (TME), immune cell fractions were inferred by deconvoluting bulk RNA expression profiles using quanTIseq (RRID:SCR_022993).

Results: Of 716 patients in the Caris dataset, 298 were treated with IO; 77 (26%) had PeM and 221 (74%) had PM. No significant differences in mutations, tumor mutation burden (>=10), PD-L1 positivity and MMR deficiency were observed between the two group of mesothelioma. PeM specimens however demonstrated significantly higher infiltration of M2 Macrophages (12 vs 8%) and lower infiltration of M1 Macrophages (4 vs 5%, both q<0.05) compared to PM, suggesting a more immunologically active microenvironment potentially influencing response to IO. IO-treated patients with PeM demonstrated significantly longer IO-OS (median 19.6 vs. 13.1 months; HR=0.56) compared to those with PM (both p<0.001, Figure).

Conclusions: Using two independent datasets, our findings highlight PeM as a biologically and clinically distinct disease, characterized by a more immunogenic tumor microenvironment and superior outcomes with IO compared to PM. These data suggest that integration of immunotherapy into the treatment course for patients with PeM may be critical to optimizing survival. Prospective validation is warranted.

PT2.15.01 A Randomized Controlled Trial on the Effect of Oncologist's Recommendations on Exercise, Sedentary, and Quality of Life in Patients With NSCLC

A. Avancini[1], L. Belluomini[1], D. Giannarelli[2], A. Borsati[3], M. Sposito[1], J. Insolda[1], J. Menis[4], P. Lavagnolo[3], D. Tregnago[1], I. Trestini[5], F. Schena[3], M. Milella[1], S. Pilotto[1]
[1]Section of Oncology, Department of Engineering for Innovation Medicine (DIMI), University of Verona and University and Hospital Trust (AOUI) of Verona, Italy, Verona/IT ,[2]Fondazione Policlinico Universitario A. Gemelli, IRCCS-Epidemiology&Biostatistic, Rome, Italy, Rome/IT ,[3]Department of Neurosciences, Biomedicine and Movement Science, University of Verona,, Verona/IT ,[4]Department of Medical Oncology, University Hospital of Verona, Verona, Italy, Verona/IT ,[5]Dietetic Service, Medical Direction, University Hospital of Verona (AOUI), Italy, Verona/IT

Introduction: Physical activity is associated with better survival in lung cancer, including patients receiving immune-based therapies. Exercise has been demonstrated to be safe and effective in mitigating lung cancer impairments and treatment-related toxicities. Several national and international societies released dedicated guidelines for patients with cancer, strongly recommending engaging in regular exercise. Nevertheless, about 70% of patients with NSCLC are insufficiently active. Promoting physical exercise requires a multidisciplinary team effort, with the oncologist being a crucial player. In this light, the O.R.E. trial aims to explore the effect of the oncologist's recommendation on exercise amount, sedentary behavior, and quality of life (QoL) in patients with NSCLC.

Methods: A single-blind, 3-arm randomized controlled trial design was applied to test the impact of i) oncologist's verbal and written exercise recommendations (EX-G) and ii) oncologist's verbal and written recommendations + dedicated exercise guidebooks (EX-GG) vs. the usual care (CG). The primary endpoint was physical exercise, evaluated using the Godin-Shepard Leisure Time Questionnaire. Secondary endpoints included sedentary habits, assessed with the Sedentary Behavior Questionnaire, and QoL, measured using the EORTC QLQ-C30. Assessments were performed at baseline, after 4 and 8 weeks. Descriptive statistics and mixed-model analysis were used to analyze data.

Results: Overall, 91 patients with NSCLC, stage I-IV (n=31 oncologist's verbal/written recommendation, n=31 oncologist's verbal/written recommendation + guidebook, n=29 control group) were recruited. After adjusting results for disease and socio-demographic characteristics, at 8-weeks, compared to CG, the EX-G reported a significant increase in total (+270.2; 95%CI: 22.2-518.3; p=0.03) and light-intensity (+235.7; 95%CI: 45.6-425.7; p=0.01) physical activity, whereas the EX-GG showed an improvement in total (+250.6; 95%CI: -7.5-508.7; p=0.05) and moderate-intensity (+145.2; 95%CI: -0.8-291.2; p=0.05) activity. No significant changes were observed for sedentary behaviors. Regarding QoL, at 4 weeks, the EX-GG demonstrated an enhancement in cognitive function (+10.1; 95%CI: 1.8-18.3; p=0.01), and EX-G of social function (15.1; 95%CI: 3.0-27.3; p=0.01) than CG. At 8 weeks, EX-GG also reported an improvement in constipation (-14.8; 95%CI: -27.9—1.8; p=0.02) over the CG. No significant differences were observed for other QoL.

Conclusions: An oncologist's recommendation, with or without the combination of a dedicated guidebook, is effective in increasing patients' physical exercise levels and some domains of QoL. Nevertheless, the introduction of a guidebook appears more efficacious in improving the moderate-intensity level. The oncologist, with a few minutes of their time, may positively change lifestyle of patients with NSCLC.

PT2.15.02 Young Lung Cancer: The Psychosocial Needs Assessment

N. Florez[1], L. Kiel[2], R. Kaufman[2], M. Horiguchi[2], R. Lederman[2], B. Bye[3], A. Morabito[2], C. Mantz[2], K. Meza[4], G. Mountzios[5], B. Ricciuti[1], B. Johnson[1], C. Pozo-Kaderman[2], S. McDonald[2], J. LoPiccolo[1], A. Enzinger[1], A. Partridge[1]
[1]Dana-Farber Cancer Institute/Harvard Medical School, Boston/MA/USA ,[2]Dana–Farber Cancer Institute, Boston/MA/USA ,[3]Young Lung Cancer Initiative, Raleigh/NC/USA ,[4]Baylor University, Houston/TX/USA ,[5]Henry Dunant Hospital Center, Athens/GR

Introduction: Young patients (≤50 years) with lung cancer (LC) represent approximately 6-10% of new U.S. LC diagnoses, and little is known about the unique psychosocial needs of this population.

Methods: "Young Lung" is the first and largest single-institution, cross-sectional cohort study designed to characterize the psychosocial needs of young patients with LC and explore differences from older patients. Adult patients with stage I-IV LC were eligible within one year of diagnosis; purposeful sampling was used to enroll equal proportions of patients younger and older than 50 years. The FACT-G questionnaire assessed four quality-of-life subscales (physical, emotional, social, and functional well-being) and FACIT-COST assessed financial distress; higher scores indicated better well-being. Descriptive statistics summarized demographics. Wilcoxon tests examined differences between younger (≤50 years) and older (>50) patients in FACT-G and FACIT-COST scores. Fisher's exact test compared differences by age group in the proportion of patients endorsing individual items.

Results: From 4/2023-12/2024, 199 patients were enrolled, 99 younger and 100 older patients. Among all patients, most (62%) identified as female, White (78%), had adenocarcinoma (61%), and were undergoing treatment (83%). Though the mean total FACT-G score for all patients was 74.5 (SD: 17.7) and was similar between the younger and older cohort (p=0.069), young patients reported worse well-being on the emotional subscale (p=0.002) and were more likely to endorse worse affect across all items on this subscale. Specifically, a higher proportion of young patients endorsed feeling anxious (50% vs 26%; p=0.001) and being worried about dying (49% vs 32%; p=0.03). Trends of higher depression rates were also endorsed by young patients, but not to a statistically significant degree (46% vs 32%; p=0.057). For all patients, the mean COST score was 25.9 (SD: 11.3), with young patients having significantly worse financial toxicity (p=0.015). A higher proportion of young patients were concerned about maintaining employment throughout treatments (42% vs 20%; p=0.002). Young patients were less likely to feel financially in control (62% vs 77%; p=0.03) and more likely to express that their LC has been a financial hardship (49% vs 21%; p<0.001).

Conclusions: Young patients with LC report significantly worse emotional distress and financial toxicity than older patients. Further research will be critical to understand and address the unique needs of this population.

Table 1: FACT-G and FACIT-COST scores among younger (≤50 years) and older (>50) patients with LC.

		Young Patients (n=99)	Older Patients (n=100)	Total	p-value

PT2.15.03 Examining the Role of Frailty Assessments in Older Adult With Lung Cancer to Identify Patient Vulnerabilities and Exploring Patient Outcomes

P.N. Papayanis, A. Poles, M.J. Fidler, M. Bednarczyk, A. Okray
Rush University Medical Center, Chicago/IL/USA

Introduction: In oncologic care, frail older adults (OA) are at an increased risk for poor treatment outcomes. The National Compressive Cancer Network recommends pretreatment frailty evaluation using a comprehensive geriatric assessment for OA to optimize treatment plans and improve outcomes. In this study, lung cancer patients were evaluated at the Rush Functional Assessment and Individualized Recommendations (FAIR) Frailty Clinic to identify at-risk patients and gaps in overall care. Patients were referred from a combination of nurse coordinator screening and treating physician referral.

Methods: A retrospective chart review was conducted on 51 patients with lung cancer who were identified to be an at-risk population by their oncologist and referred to the FAIR Clinic between October 2019 and May 2024 for frailty assessment. We collected data on diagnosis, patient demographics, symptoms, functional assessments, post-assessment recommendations, and treatment outcomes. Due to sample size data, descriptive analysis was used.

Results: The average age was 77.2 years old; with 67% female. The racial breakdown was 53% African American, 33% Caucasian, and 12% Hispanic. The most common diagnosis was non-small cell lung cancer 88%, and the most common stages at the time of evaluation were SIII 45.1% and then SIV 23.5%. The average BMI was 26.33, and 78.85% of patients had either a reported or documented weight loss exceeding 10 pounds over the past year. Average scores and ranges for the most notable assessments were: Montreal Cognitive Assessment 17.07 (5-27), Fried Frailty Phenotype (FFP) 2.3 (0-5). Patients had an average of two referrals made per visit, the most common being physical and occupational therapy, social work, and dietitian. After evaluation, Treatment outcomes varied: 11 patients received no further treatment (FFP 3.2, 2 hospitalizations, 3 deaths), 12 received radiation alone (FFP 3.0, 1.5 hospitalizations, 2 deaths), and 27 received systemic therapy with or without radiation/surgery (FFP 2.1, 2.1 hospitalizations, 6 deaths).

Conclusions: Our data demonstrates the majority of the patients referred to the FAIR clinic were pre-frail, cognitively impaired, with significant comorbidity, and ethnically diverse, with a higher population of African American patients compared with the lung cancer patient population at Rush (35%). We identified needs outside of oncologic treatment, including therapy services and social work support. While descriptive, our data suggests patients who did not receive treatment were frailer than those that did. Patients who did receive systemic treatment had a high incidence of treatment-related hospitalizations. Overall, our data highlights the value of frailty clinics in identifying patient vulnerabilities and assisting in individualized treatment plans, though few eligible patients with stage IV lung cancer diagnoses attended the evaluation from a program servicing 700 lung cancer patients annually. Future efforts should focus on closer monitoring of patients receiving systemic treatment and improving access for patients with stage IV cancer, particularly those from lower socioeconomic status.

PT2.15.04 Impact of Physical Exercise on Quality of Life in Patients With Advanced Lung Cancer

A. López Martín[1,2], A. Barrera-Garcimartín[3], P. Trejo-Martín[2], C. Cordente-Martínez[3], A. Garrido-García[1,2], A. Peñalver-Vera[1], I. Refoyo[3], B. Nafría[1], L. Abalo[1,2], S. Fraile-Barragan[1], M. Matute[1], M-J. Echarri-González[1,2], G. Ruíz-Martín[1,2], M. Marquina[3]
[1]Hospital Universitario Severo Ochoa, Leganes/ES ,[2]Universidad Alfonso X El Sabio, Villanueva de la Cañada/ES ,[3]Universidad Politécnica de Madrid, Madrid/ES

Introduction: Recent research has increasingly highlighted the benefits of physical exercise for persons with cancer, particularly in improving quality of life, functional capacity, and overall well-being. Regular PE has been associated with reduced cancer-related fatigue, improved muscle strength, better cardiorespiratory fitness, and enhanced emotional resilience. Additionally, it helps alleviate symptoms such as dyspnea, anxiety, and depression, which are common in people with advanced lung cancer (LC). Despite these benefits, the optimal type, intensity, and frequency of exercise, as well as its role in disease progression and quality of life, remain insufficiently defined in this population. In this abstract, we present the observed changes in quality of life and physical condition in persons with advanced LC enrolled in an ongoing study that comprehensively evaluates the effects of a structured exercise program, assessing its impact on physical and emotional well-being.

Methods: This quasi-experimental, prospective observational study implemented a supervised and structured physical exercise intervention program led by a multidisciplinary team consisting of oncologists, nutritionists, nurses, and professionals in Physical Activity and Sports Sciences. The program consisted of two weekly 60-minute sessions, each including:

- Warm-up (8-12 minutes): Joint mobility and locomotor exercises.
- Main session (40-45 minutes): Targeted strength, mobility, aerobic, and relaxation exercises.
- Cool-down (12-15 minutes): Group discussions, relaxation exercises, and collective reflection.

Quality of life was assessed using the EORTC QLQ-C30 and EORTC QLQ-LC29 questionnaires, along with the Hospital Anxiety and Depression Scale (HADS), administered at baseline and after the 3-month intervention. Physical condition was evaluated using the 5-Repetition Sit-to-Stand Test.

Results: The study enrolled 29 participants between November 2024 and March 2025. Preliminary data from 10 participants (4 men, 6 women; mean age: 68 years; 9 with stage IV non-small cell lung cancer, 1 with stage IIIc small cell lung cancer) revealed significant improvements in the QLQ-C30 functional scales: overall functional score ($p=0.0395$) and emotional functioning ($p=0.0135$). No significant changes were observed in the QLQ-LC29 scale. The HADS indicated a significant reduction in total anxiety scores ($p=0.044$). Additionally, significant improvements were observed in the 5-Repetition Sit-to-Stand Test ($p<0.05$). The adherence rate to the exercise program was 71%.

Conclusions: People with LC benefit from regular, supervised physical exercise, experiencing improvements in quality of life, functional capacity, and reductions in anxiety levels associated with the disease. Routine inclusion of these programs as part of non-pharmacological treatment strategies could contribute to the overall well-being of people with LC.

PT2.16.01 Current Patient, Caregiver and Provider Attitudes Toward Use of AI in Lung Cancer Patient Navigation

S. Monestime[1], A. Ciupek[1], M. Reiss[1], D. Hicks[2], C.A. Granville[1]
[1]GO[2] for Lung Cancer, Washington/DC/USA ,[2]GO[2] for Lung Cancer, San Carlos/CA/USA

Introduction: Lung cancer care is complex due to disease heterogeneity and the need for personalized treatment strategies. Additionally, current lung cancer resources are fragmented by topic, which makes it challenging for individuals to find the information they need and determine what is relevant to them. These factors make providing tailored, effective support services for each patient challenging, yet access to resources can improve survival. Artificial Intelligence (AI)-based approaches that leverage machine learning and natural language processing offer a promising solution to enhance patient education and navigation. To better understand attitudes toward the use of AI in navigation of patients with lung cancer, GO2 for Lung Cancer (GO2), a lung cancer patient-advocacy organization, implemented a brief survey of both patients and providers in our community.

Methods: As part of a quality improvement initiative, we conducted a cross-sectional survey between January 27 and February 7, 2025, to gather feedback on the feasibility and acceptability of a proposed AI-powered navigation tool for individuals impacted by lung cancer. Participants included healthcare professionals (HCPs) involved in lung cancer navigation and individuals diagnosed with or caring for someone with lung cancer. Survey content was informed by the Consolidated Framework for Implementation Research (CFIR) to ensure alignment with key implementation domains. Two structured electronic surveys were developed: a 13-item survey for HCPs a 10-item survey for patients and caregivers. The HCP survey collected information on clinical background, years of experience, navigation responsibilities, and perspectives on AI integration, including perceived usefulness, confidence in AI-generated information, comfort, and leadership support. The patient and caregiver survey explored familiarity with AI tools, comfort with receiving AI-generated health information, perceived ease of use, willingness to share health history, and desired tool features. Surveys were distributed through GO2 outreach channels to inform the design and future implementation of the navigation tool. Descriptive statistics were used to summarize responses.

Results: Of the 98 responses collected, 42 were from HCPs and 56 were from patients or caregivers. Among HCPs, the most reported backgrounds were pharmacists (42.9%), physicians (26.2%) and nurses (21.4%), with the majority of HCPs (33%) having over 21 years of experience. The survey revealed that over 95% of providers believe AI could improve efficiency and decision-making in patient navigation. Additionally, 90% of providers reported they were likely or very likely to integrate AI-powered patient navigation if a tool was provided. Furthermore, 69% of HCPs believed that patients would respond positively to the use of AI in their care. For patients/caregivers, the survey found that 67% rely on online resources for information. Only 20% expressed discomfort with the use of AI in providing information, while 62.2% were hesitant but open to its use, and 17.8% reported they would have no issues. Patients/caregivers cited simplified medical information (63%), accessing clinical trials (40.9%), and symptom management (38.6) as their top reasons for interest in AI-driven support.

Conclusions: Patients with lung cancer, caregivers, and care providers recognize the potential benefits of AI in care. However, addressing concerns around mistrust and usability will be crucial for widespread adoption.

PT2.16.02 Patients Who Reach Clinical Trials and Those Who Do Not,A Structural Analysis of Access Disparities in Japan

K. Hasegawa[1], H. Katayama[1], S. Hamasaki[2], S. Hamamatsu[3], A. Murakami[4], H. Saito[4], K. Kachi[3]
[1]NPO Lung Cancer Patient Association ONE STEP, YOKOHAMA/JP ,[2] Hmedi-solution, TOKYO/JP ,[33]Hmedi-solution, TOKYO/JP ,[4]Teikyo University Graduate School of Public Health, TOKYO/JP

Introduction: Clinical trials are an essential process for scientifically evaluating the efficacy and safety of new treatments and hold significant potential to expand future therapeutic options. To ensure reliability and external validity, it is vital that patients from diverse backgrounds—including differences in age, gender, values, and socioeconomic conditions—can participate equally. However, recent studies in Japan have revealed multiple barriers in patient access to clinical trial information. A 2021 national survey showed that while about half of patients obtained information through websites, information provided by healthcare professionals remained limited. Moreover, the usability of clinical trial search platforms and difficulty understanding technical terminology were reported as significant obstacles. Against this backdrop, the present study aims to visualize the process by which lung cancer patients who express interest in clinical trials actually reach the point of potential participation. We focused on the key turning point of physician referral and analyzed the factors influencing whether or not patients received a trial recommendation, in order to clarify the structural disparities in access.

Methods: From May 20 to June 7, 2024, a web-based survey was conducted targeting lung cancer patients, their families, and bereaved family members who had shown prior interest in clinical trials. Among the 253 total respondents, 148 who had actively considered trial participation were analyzed. We compared 58 patients who were referred to a trial by their physician with 90 who were not. Variables such as type of medical institution (specialized cancer hospital or not), patient behavior (whether they searched or proactively requested trial information), and attitudes toward clinical trials were analyzed using logistic regression.

Results: Patients who expressed interest in trial participation to their physician were significantly more likely to be referred (OR: 4.70, 95% CI: 1.83-12.75). Those receiving care at cancer centers were also more likely to be referred (OR: 4.28, 95% CI: 1.71-11.09). In contrast, patients who searched for trials but did not communicate their interest to their physician had a notably lower likelihood of being referred (OR: 0.04, 95% CI: 0.01-0.12), showing a negative association.

Conclusions: This study highlights that access to clinical trials strongly depends on patients' proactive communication and the type of healthcare institution they attend. Even when patients are interested and seek information, that alone is insufficient—dialogue with physicians plays a crucial role. The current system, where trial implementation is concentrated in certain institutions, may be contributing to regional and institutional disparities. To expand the opportunity for a broader range of patients to participate in clinical trials, it is essential to develop neutral and equitable systems of information provision by healthcare professionals, along with user-friendly environments where patients can easily search, understand, and evaluate options. Furthermore, clinical trial information should not be viewed merely as guidance, but as part of a process that supports patients in making the best possible decisions.

PT2.16.03 Overcoming Lung Cancer Nihilism and Fatalism to Foster Compassion, Empathy, and Support

J.L. Studts[1], L. Carter-Bawa[2], N. Stigma and Nihilism Task Group[3]
[1]University of Colorado Cancer Center, Aurora/CO/USA ,[2]Hackensack Meridian Health, Nutley/NJ/USA ,[3]American Cancer Society, Atlanta/GA/USA

Introduction: Lung cancer remains the leading cause of cancer death worldwide. Despite significant advances in lung cancer risk reduction, screening, treatment, and survivorship, deeply entrenched nihilism and fatalism continue to shape public and clinical perceptions, impeding access to optimal care and life-saving interventions. As part of the American Cancer Society National Lung Cancer Roundtable, the Stigma and Nihilism Task Group (S&NTG) recently considered efforts to address the pervasive diagnostic and treatment nihilism that is regrettably common in society and healthcare settings regarding lung cancer and propose evidence-based strategies to shift the narrative toward one of hope, empathy, and progress.

Methods: A multidisciplinary team of experts conducted a comprehensive review of the psychological, social, and systematic factors contributing to lung cancer nihilism and fatalism. The team synthesized existing literature on the psychological and social impact of nihilism/fatalism, communication strategies, and public perceptions. They also identified key opportunities for intervention at individual, clinician, and societal levels.

Results: The findings highlight several actionable strategies to address nihilism and fatalism in lung cancer care.

1. Empathic Communication: Using person-first language and avoiding stigmatizing labels reduces bias and enhances patient engagement.
2. Clinician Education and Screening Promotion: Addressing clinician hesitancy in recommending lung cancer screening is critical to increasing uptake.
3. Public Awareness and Media Representation: Enhancing accurate portrayals of lung cancer in media and public discourse can counter outdated stereotypes and stigma.
4. Addressing Tobacco Stigma Without Blame: Non-judgmental approaches to smoking history can foster trust and improve engagement in cessation and screening efforts.
5. Mental Health and Supportive Care: Given the high rates of distress and suicide among individuals with lung cancer, integrating mental health support is essential.
6. Research Funding and Advocacy: Increased investment in lung cancer research and advocacy efforts is needed to support continued progress in care and policy.

Conclusions: Lung cancer care has undergone transformative advances, yet nihilism and fatalism remain persistent barriers to progress. A concerted effort across healthcare, public health, advocacy, and media is required to realign public perception with the current reality of lung cancer care—one that is increasingly characterized by early detection, effective treatment, and improved survival. The recommendations presented offer a roadmap to fostering a culture of compassion, reducing stigma, and optimizing outcomes for individuals at risk for or diagnosed with lung cancer.

PT2.16.04 Advancing Lung Cancer Advocacy in Low- and Middle-Income Countries

C. Egwuenu[1], J. Feldman[2], U.B. Roy[3], J. Isaac[1], L. Pretorius[4], V. Tomar[5], U. Shagaya[6]
[1]Move Against Cancer Africa, Abuja/NG ,[2]EGFR Resisters Lung Cancer Patient Group, Chicago/IL/USA ,[3]LUNGevity Foundation, Chicago/IL/USA ,[4]Campaigning for Cancer, Randburg/ZA ,[5]Rise To Survive Cancer, New Delhi/IN ,[6]National Hospital Abuja, Abuja/NG

Introduction: Lung cancer remains a leading cause of cancer-related deaths worldwide, with an increasing burden in low- and middle-income countries (LMICs). Challenges such as lack of awareness, late diagnosis, and limited access to treatment highlight the urgent need for patient advocacy. The International Association for the Study of Lung Cancer (IASLC) hosted a Patient Advocacy Workshop at the 2025 Pan-Africa Conference on Lung Cancer to identify frameworks to foster multi-sectoral collaboration and best practices for sustainable advocacy strategies in Africa.

Methods: All conference attendees received information about the Workshop. Those who expressed interest received an online Pre-Workshop Survey to assess challenges in lung cancer care in individual countries and patient advocacy experience. The Workshop included formal presentations, panel discussions, and a group discussion during which participants answered 5 key questions on advocacy priorities. The information recorded from panel and group discussions was analysed thematically. An evaluation survey followed the Workshop.

Results: Forty-two conference attendees from 11 countries, 8 of which were on the African continent, participated in the Workshop. Pre-Workshop Survey: 25/42 (60%) responded to the Pre-Workshop Survey, which identified financial cost, limited healthcare infrastructure, and late detection of lung cancer as the three top challenges. Nine had participated in patient advocacy at the hospital level. The findings from this survey were used to guide the discussion agenda for the in-person Workshop in Accra, Ghana. Workshop Discussion: Two case studies were presented: the Move Against Cancer Africa oncology phlebotomy station and the EGFR Resisters. Both projects highlight the power of community engagement and how partnerships between advocates and healthcare institutions lead to long-term changes in cancer care. The discussion created a framework of four key pillars of effective advocacy: connection, community, collaboration, and communication. It also outlined three levels of advocacy progressing from self to community to systemic change. Workshop Group Discussion: We identified 22 themes for the guiding questions answered at the in-person Workshop. The guiding questions included: What does advocacy mean to you? What are your priorities for 2025? What resources are needed to accomplish your priorities? How will collaboration help bring other resources? What are the opportunities for advocacy in your country? Priorities identified were: Investing in resource-sharing platforms, translating and adapting patient and caregiver materials, and developing local pilot programs in collaboration with advocates to enhance cancer advocacy efforts. Additionally, professional organizations should allocate dedicated resources to support advocate development in LMICs, such as scholarships for training and global conferences. Post-Workshop evaluation: 21/42 (50%) responded to the evaluation. 90% of participants were satisfied with the Workshop; 100% stated they would recommend it to others. The top three actions participants felt equipped to take were: advocate for better healthcare policies (81%), share information on early detection (71%), and support lung cancer patients/their families emotionally (62%).

Conclusions: The Workshop highlighted key frameworks for multi-sectoral collaboration, including deploying the four pillars for advocacy. Moving forward, sustained investment, collaboration with patient advocates, and dedicated (digital) professional development opportunities in LMICs will be critical to strengthening advocacy impact.

PT2.16.05 Survivorship Needs for Patients With NSCLC Treated With Oral Targeted Therapies

M. Guo[1], C. Burley[2], Y. Wang[2], J. Dobbs[1], C. Eaton[2], S. Olson[2], M.L. Hsu[3], J. Feliciano[1]
[1]Johns Hopkins Hospital, Baltimore/MD/USA ,[2]Johns Hopkins Bayview Medical Center, Baltimore/MD/USA ,[3]University Hospitals Seidman Cancer Center, Cleveland/OH/USA

Introduction: Oral targeted therapies (OTT) for treatment of oncogene-driven non-small cell lung cancer have contributed to a growing population of long-term lung cancer survivors (LCS). OTTs provide more patient-specific treatment options compared to standard cytotoxic chemotherapy, easier oral route of treatment administration, and more tolerable side effects due to less off-target effects. However, the survivorship needs of LCS who received OTT, including physical, psychosocial, and care delivery needs, are not well-defined.

Methods: LCS (defined as alive ≥1 year from diagnosis) treated at Johns Hopkins between 2020-2024 were invited to complete a needs assessment survey measuring patients' perspectives on survivorship needs across 4 subscales (physical, social, emotional, medical) rated on a 5-point Likert scale (1=no need, 5=highest need; score 2+ indicating need endorsement). Demographic and clinical information, including lung cancer treatment regimens and intent (palliative vs curative), were collected by chart review and survey response. Patients with >80% survey completion were included for analysis. Wilcoxon rank sum or Kruskal-Wallis tests identified demographic characteristics associated with greater needs among patients who received OTT. As patients on curative-intent therapy were expected to have significantly fewer needs than patients on palliative-intent therapy, a sub-group analysis was conducted to examine differences in needs by OTT-history among patients on palliative-intent therapy only.

Results: 428 patients were invited to complete the needs assessment survey, of which 307 were included for this analysis. Median age was 68, most were female (59.9%), Caucasian (73.9%), and had ECOG performance status 0-1 (91.5%) at time of survey. In terms of treatment history, 36.2% (n=111) had ever received OTT and 60.9% (n=187) were on palliative-intent for most recent line of therapy. More than half of patients who had received OTT endorsed emotional needs of living with uncertainty (80.0%) and fear of recurrence (78.2%). Common physical needs in the ever-OTT cohort were fatigue (82.7%), memory/concentration (64.9%), and hair/skin changes (63.6%). Amongst all ever-OTT patients, age <65 (p=0.002), non-Caucasian race (p=0.024), and non-employed employment status (p=0.022) were identified as factors associated with greater number of social needs. Key comparisons in rates of need endorsement by ever- and never-OTT patients on palliative-intent therapy were identified (Table 1).

Conclusions: Survivorship needs are highly prevalent among LCS patients, regardless of their history of receiving OTT. Certain demographic factors are associated with greater number of social needs amongst ever-OTT patients, suggesting disparities in unmet survivorship needs.

Table 1. Percent of patients on palliative-intent therapy who endorsed needs (Likert scale 2-5)

Need	Ever-OTT (n=102)	Never-OTT (n=95)	P-value
Emotional Needs			
Living with uncertainty	81.2%	74.1%	0.128
Fear of recurrence	77.2%	82.1%	0.697
Physical Needs			
Fatigue	84.1%	80.0%	0.877
Memory/concentration	64.7%	61.9%	0.990
Hair/skin changes	64.3%	46.4%	0.0165
Sleep disturbances	61.8%	73.5%	0.0691
Bowel/bladder dysfunction	59.4%	43.9%	0.0628
Social Needs			
Managing daily activities	45.2%	40.0%	0.375
Returning to work	31.1%	26.3%	0.107
Financial concerns	45.9%	52.5%	0.651

PT2.17.01 Point-Of-Care Rapid Tissue Diagnosis at Primary Consultation: Optimizing TIME to Treatment in the Neoadjuvant Era

B. Kidane, S. Gowing, L. Tan, G. Qing
University of Manitoba, Winnipeg/MB/CA

Introduction: Tissue diagnosis and molecular testing are necessary to allow for locally advanced or advanced lung cancers. Challenges and delays in achieving this reliably can result in lack of access to the survival advantages of neo-adjuvant therapy or best therapy for unresectable advanced cancers . We assessed the diagnostic yield, sufficiency for molecular testing and resource utilization improvements of a thoracic surgeon-led, point-of-care ultrasound-guided biopsy program in a single-payer publicly-funded healthcare system.

Methods: A prospective cohort study was performed of consecutive patients undergoing ultrasound-guided percutaneous biopsies performed by thoracic surgeons from June 2021 to March 2025 at a tertiary Canadian institution. Diagnostic yield, sufficiency for molecular testing and resource utilization improvements were analyzed.

Results: A total of 211 patients underwent point-of-care ultrasound percutaneous biopsy for locally-advanced or advanced thoracic cancers. Tissue diagnosis was obtained in 89.6% of patients (n = 189). There was sufficient tissue for molecular testing in 95.2% (n=180) of these patients. Due to the rapid point-of-care timing of the biopsy, successful repeat biopsy was able to be done promptly in our clinic (i.e. repeat percutaneous biopsy or EBUS/EUS) without being a source of delayed care. There was 1 post-procedure pneumothorax (adverse event rate 0.5%). This program significantly reduced time-to-treatment by an average of 23 days ($p<0.05$). Reduction was also identified, to a lesser extent, to other patients during the same time period. Root cause analysis showed that this improvement was due to increased access to EBUS, EUS, CT-guided biopsies that were no longer needed by these 189 patients.

Conclusions: Thoracic surgeon-led ultrasound-guided biopsies can be done in an outpatient clinic setting with high diagnostic accuracy, high yield/sufficiency for molecular testing and can reduce time-to-treatment in a clinically-significant way. This benefit at the patient-level appears to also be extended downstream at the system-level by offloading demands on other resources, thereby reducing time-to-treatment for other patients. This appears to be a promising model, especially for low-moderate resource settings.

PT2.17.02 Impact of Timely Treatment Initiation on Outcomes in Non-Small Cell Lung Cancer. A Registry Based Observational Study

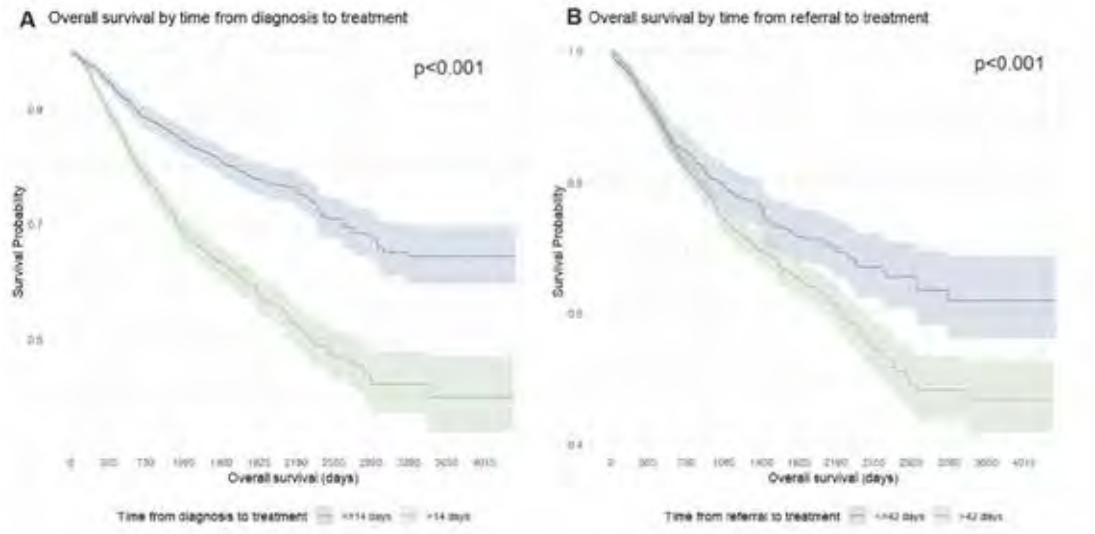
Introduction: Lung cancer is the leading cause of cancer death in Australia, with evidence of unwarranted variation in clinical care. Timeliness recommendations have been made in international guidelines, although previous studies exploring the effect of timeliness on survival in NSCLC have revealed conflicting results.

Methods: We performed an observational cohort study of all cases of Stage I-II NSCLC in the Victorian Lung Cancer Registry (VLCR), between July 2011 and May 2023. Timeliness intervals were defined by the Australian Optimal Care Pathway for people with lung cancer. A diagnosis-to-treatment interval (DTI) of <14 days and referral-to-treatment interval (RTI) of <42 were defined as timely. The effect of timeliness on overall survival was determined using Cox proportional hazards regression.

Results: We identified 3,016 cases of Stage I-II NSCLC (52% Male). Patients receiving timely treatment (n=1,204, 42%) were younger (median 69 vs 72 years, p <0.001) and never smokers, with fewer comorbidities and better performance status. Patients undergoing surgical resection (n=1,989, 66%) were more likely to receive timely care, whereas those undergoing systemic treatment, radiotherapy, or referred to palliative care were less likely (p<0.001). Median overall survival to census date for timely DTI and RTI were 1,100 days (IQR 585, 1,815) and 1,337 (IQR 713, 2,077) respectively, vs untimely 1,439 (IQR 746, 2,203) and 1,033 (IQR 588, 1,653) p<0.001 Table 1. Both timely DTI and RTI were associated with significantly lower mortality risk (DTI HR 0.57, 95% CI 0.49-0.67, p <0.001, RTI HR 0.75 95% CI 0.63-0.9, p 0.002) Figure 1.

Conclusions: Timely treatment of Stage I-II NSCLC was associated with improved survival, although most cases did not meet recommended timeliness intervals. With lung cancer screening soon to be implemented in Australia, there is a strong impetus to investigate the barriers to timely access to care and help guide future resource allocation.



Time Interval	Median (IQR) (days)	<7 days n (%)	8-14 days n (%)	15-28 days n (%)	29-42 days n (%)	>42 days n (%)	Proportion meeting timely care
RDI	35 (18, 58)	250 (8.3%)	263 (8.7%)	605 (20%)	503 (17%)	1077 (36%)	37%
DTI	23 (0, 45)	1084 (36%)	120 (4.0%)	410 (14%)	482 (16%)	790 (26%)	40%
RTI	64 (43, 93)	34 (1.1%)	56 (1.9%)	193 (6.4%)	348 (12%)	1948 (65%)	35%

n.b. ~10% of cases missing definitive referral date = Meets definition of timely care

PT2.17.03 Accelerated Biological Aging Is Correlated With the Incidence and Poor Prognosis of Young Lung Cancer

Y. Liao, R. Gao, J. Zhong, J. Wang
Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing/CN

Introduction: While lung cancer is predominantly diagnosed in seniors, the incidence of young lung cancer (≤45 years) is rising. Current screening guidelines primarily target older populations, leaving younger individuals at risk of delayed diagnosis and poor outcomes. Accelerated biological aging, measured by Phenotypic age acceleration (PhenoAgeAccel), has been implicated in cancer susceptibility, yet its role in young lung cancer remains poorly understood.

Methods: A multicenter case-control study in China (120 young lung cancer patients and matched 120 health volunteers) and validation with the UK Biobank were conducted. PhenoAgeAccel was calculated from clinical hematological and biochemical parameters to assess accelerated biological aging. Logistic regression was used to estimate the relationship between PhenoAgeAccel and the lung cancer risk.

Results: Young lung cancer patients exhibited significantly higher PhenoAgeAccel than healthy volunteers ($P < 0.001$), with a dose-dependent increase in cancer risk (OR: 25.8, 95% CI: 8.94-88.9, for high PhenoAgeAccel). Further subgroup analysis based on chronological age indicated a stronger impact of PhenoAgeAccel on cancer risk in earlier adulthood. Senior lung cancer patients exhibited weaker or non-significant associations. Survival analysis demonstrated that higher PhenoAgeAccel was associated with worse overall survival in young lung cancer patients (HR = 2.16, 95% CI: 1.04-4.49). The UK Biobank cohort confirmed these findings.

Conclusions: Accelerated biological aging is strongly associated with higher young lung cancer risk and poorer prognosis. PhenoAgeAccel may serve as a potential cost-effective biomarker for early detection and risk stratification for this specific population.

Introduction: The International Association for the Study of Lung Cancer (IASLC) is committed to implementing and promoting Diversity, Equity, and Inclusion (DEI) within its organization and iteratively assessing DEI needs and perceptions. Here, we report the first survey-based evaluation of inclusive practices and challenges within the IASLC.

Methods: We administered an online, anonymous survey through QualtricsXM that was shared via the IASLC membership list. Additional outreach took place via social media and direct messaging in WhatsApp™. The survey was available in English, Spanish, Japanese, Italian, French, Portuguese, Korean, and Mandarin. Throughout all outreach efforts, non-IASLC members were also encouraged to participate. Statistical analyses were conducted using R 4.4.0; reported percentages reflect the number of respondents for each question. Pearson's Chi-squared tests or Fisher's exact tests were used to compare responses by subgroups of interest.

Results: A total of 1234 individuals started the survey; 707 (57.3%) partially or entirely completed the survey and were included in this analysis (Table 1). Most reported that the IASLC is always or usually inclusive (always, usually) regarding race/ethnicity (51.5%, 32.5%), gender (58.8%, 29.1%), age (51.4.%, 32.1%), family status (52.1%, 29.7%), socioeconomic status (44.6%, 32.2%), sexual orientation (54.8%, 27.8%), disability status (45.0%, 32.2%), religion (54.5%, 27.3%), profession (47.4%, 32.0%), and language (41.2%, 29.2%). Compared to non-Latin American respondents (n=578), Latin Americans (n=65) were more likely to report non-inclusivity regarding language (43.3% vs 27.5%; p=0.011). Few respondents reported experiencing or witnessing discrimination at IASLC events due to age (experienced, witnessed) (4.4%, 4.7%), disability status (1.6%, 1.8%), gender (6.5%, 6.6%), family status (2.8%, 1.7%), religion (2.0%, 1.8%), sexual orientation (1.8%, 2.5%), language (6.9%, 5.5%), or race/ethnicity (5.7%, 6.4%). Compared to non-Asians (n=479), individuals practicing in East and Southeast Asian countries (n=166) were more likely to report having experienced discrimination due to primary language spoken (13.3% vs 4.4%; p=<0.001). Among all participants, few (12.1%) reported experiencing barriers to accessing IASLC resources, though this was more prominent among members from Latin America (n=65; 23.1% vs 10.8%; p=0.004) and mid-career faculty (n=224; 17.4% vs 10.0%; p=0.007). Conference assistance, increased resources for members, and diverse representation at conferences were common responses regarding how to improve inclusivity. The need to embed DEI principles within the IASLC was reported favorably by respondents, with 39.8% strongly agreeing and 39.0% agreeing.

Conclusions: Survey respondents reported favorable views regarding inclusive practices within the IASLC. Implementing strategies to increase language inclusivity could improve the experience of IASLC members.

PT2.17.05 Benefits of Adjuvant Alectinib in ALK+ Early-Stage Non-Small Cell Lung Cancer, Recurrences Avoided and Savings for the Spanish Health System

J. de Castro[1], R. Bernabé[2], V. Escudero[3], F. Gutiérrez[4], M. Majem[5], R. Gordo[6], I. Arroyo[6], S. Arranz[7], R. Collado[3]
[1]Hospital Universitario La Paz, IdiPAZ, Madrid/ES ,[2]Hospital Universitario Virgen del Rocío, Sevilla/ES ,[3]Hospital Universitario Gregorio Marañón. Instituto de Investigación Sanitaria Gregorio Marañón, Madrid/ES ,[4]Complejo hospitalario Universitario de Canarias, Instituto de Investigación Sanitaria de Canarias (IISC), La Laguna (Tenerife)/ES ,[5]Hospital de la Santa Creu i Sant Pau, Barcelona/ES ,[6]Roche Farma, Madrid/ES ,[7]Hygeia Consulting S.L., Madrid/ES

Introduction: More than half of patients with resectable early non-small cell lung cancer (eNSCLC) experience disease recurrence within 5 years. Approximately 3-5% of eNSCLC patients have ALK rearrangements, in whom adjuvant alectinib has shown a significant benefit in disease-free survival (DFS) compared to platinum-based chemotherapy (PbCH). The aim of this analysis was to quantify the potential number of disease recurrences avoided with the introduction of adjuvant alectinib in comparison to the current adjuvant PbCH for ALK+ eNSCLC over the next 10 years in Spain, together with the associated savings in the advanced disease.

Methods: An epidemiological model has been developed to estimate the number of recurrences after adjuvant treatment of early-stage (IB ≥4cm - IIIA [UICC/AJCC 7th edition TNM Classification]) ALK+ NSCLC over the next 10 years (2025-2035) in Spain. Two scenarios were compared, including adjuvant treatment with alectinib versus 4 cycles of adjuvant PbCH. The target population was estimated over the 10-year time horizon based on literature data. Alectinib market introduction was assumed at 85% in the first year, reaching a maximum share of 98% in the fifth year. Recurrence probabilities were obtained from DFS and overall survival data from the ALINA study. The cost of recurrences was obtained from the literature (euros of 2025). The sources used for epidemiological estimation, relapse probabilities and relapse costs were validated by an expert panel.

Results: The target population of patients with ALK+ eNSCLC after complete tumour resection was estimated from 98 individuals in 2025 to 122 in 2035. For the 10-year time horizon, the model projected 680 recurrences in the adjuvant PbCH scenario and 341 relapses in the adjuvant alectinib scenario. The evolution of recurrences in both scenarios is shown in Figure 1. The 339 recurrences potentially avoided with adjuvant alectinib over the next 10 years (estimating that 264 of them would be treated with systemic therapies at progression disease) would result in savings of 46,4 million euros for the Spanish National Healthcare System, an average saving of around €4,6 million/year. Scenario sensitivity analyses provided a range of 42,3 to 49,3 million euros of savings.

Conclusions: The use of adjuvant alectinib in patients with resected ALK+ eNSCLC would substantially reduce the number of recurrences over the next 10 years, resulting in significant cost savings in the management of the advanced disease for the Spanish National Healthcare System.

Figure 1. Evolution of new recurrences over time estimated by the epidemiological model.

P1.04.01 Stage Shift and Then Some - St. Elizabeth Healthcare's Notable Journey, 50,000 Screens Later

M.R. Gieske, D. Alkapalan, I.A. Budhani, E. Fahey, J. Ries
St Elizabeth HealthCare, Edgewood/KY/USA

Introduction: St. Elizabeth Healthcare, a community hospital system in Northern Kentucky and Southeastern Indiana, serving over 400,000 patients, launched its lung cancer screening program (LCSP) in 2013. Over a decade later, the program has not only exceeded benchmarks set by the National Lung Screening Trial but continues to demonstrate increasingly profound stage migration. Our sustained, data-informed, and team-based approach has significantly altered the trajectory of lung cancer detection in our region, resulting in both earlier diagnosis and improved outcomes.

Methods: A weekly multidisciplinary nodule review board evaluates Lung-RADS 4 and suspicious incidental cases to ensure timely, cost-effective, and coordinated diagnostic workup with the least risk to the patient. Three dedicated LCS nurse navigators facilitate patient and provider communication and care coordination for both the LCSP and incidental nodule program. All lung cancer screening diagnoses are entered into a compendium that tracks stage, demographics, and timeliness of care. Performance metrics across 41 screening sites and 210 primary care providers are collated quarterly and shared across our system. Our Population Health Support Services team of twelve RN outreach specialists actively supports patients with follow-up and tracks order completion to improve uptake and enhance adherence.

Results: As of early 2025, more than 50,000 low-dose CT screenings have been completed, yielding over 500 stage I lung cancers. In 2024, 151 lung cancers were diagnosed through screening; 72.2% (n=109) were stage I, and 76.8% (n=116) were early stage (I or II). Notably, since 2022, early-stage lung cancer diagnoses have surpassed late-stage diagnoses across our healthcare system. Between 2015 and Q3 2024, late-stage cancers declined 30.3 percentage points, a rate over 3.5 times faster than national trends. Q4 registry data is pending. A cornerstone chart presented at the 2025 European Lung Cancer Congress underscores this shift (see Figure 1). Additionally, a stage migration analysis from 2015 - 2023 showed that 70.0% of screen-detected lung cancers were found at stage I, compared to 36.3% in the non-screened group. Our uptake compares favorably with the national average of 16.0%, at 51.7% of eligible attributed patients.

Conclusions: Our results demonstrate that a comprehensive, team-based lung cancer screening initiative can progressively reduce late-stage cancer diagnoses and transform care pathways. This work and the advancements in lung cancer diagnostics and treatment are collectively changing the narrative on lung cancer. With maturity and sustained provider engagement, community-based programs can not only replicate clinical trial outcomes but serve as national models of scalable impact.

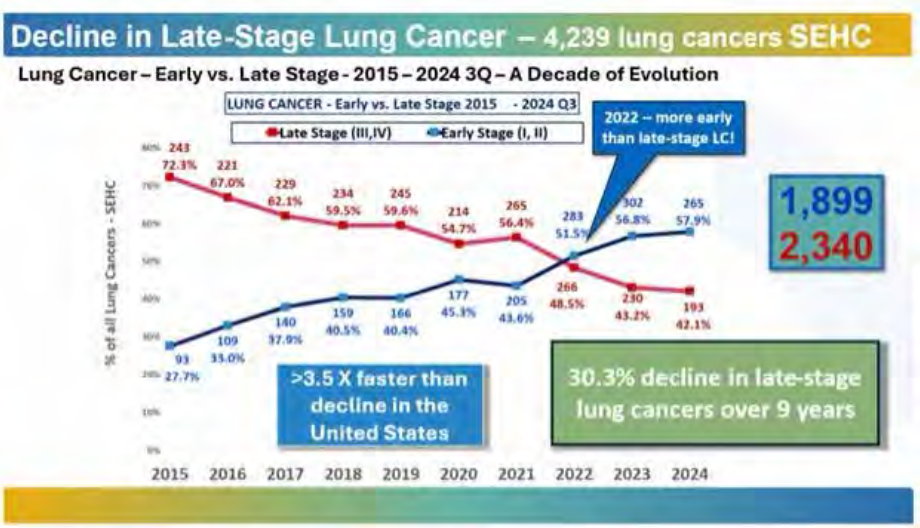

Figure 1. Decline in Late-Stage Lung Cancer at St. Elizabeth Healthcare (2015–3Q 2024). Early-stage lung cancer diagnoses (blue line) surpassed late-stage (red line) in 2022, driven by a decade of consistent LDCT screening programmatic efforts. Total lung cancers over 9 years: 4,239

P1.04.02 Performance of AI Vs. Radiologists in the 4-IN-THE-LUNG-RUN Lung Cancer Screening Trial: Annual Follow-Up Results

A.N.H. Walstra[1], B. Jiang[1], D. Han[1], I. Schuldink[1], M. Heuvelmans[1,2,3], J.W.C. Gratama[4], M. Silva[5], C. Van Der Aalst[6], H.J. De Koning[6], M. Oudkerk[1,2]
[1]Institute for Diagnostic Accuracy, Groningen/NL ,[2]University Medical Center Groningen, Groningen/NL ,[3]Amsterdam University Medical Center, Amsterdam/NL ,[4]Gelre Hospital, Apeldoorn/NL ,[5]University of Parma, Parma/IT ,[6]Erasmus Medical Center (EMC), Rotterdam/NL

Introduction: Lung cancer screening (LCS) with low-dose computed tomography (LDCT) has demonstrated significant lung cancer-related mortality reduction among high-risk individuals. Artificial intelligence (AI) is widely used as a secondary or concurrent reader in LCS. However, its role as a first reader could reduce radiologists' workload by effectively ruling out negative cases. This study evaluates AI as a first reader in the annual screening round of the European 4-IN-THE-LUNG-RUN (4ITLR) LCS trial, comparing its negative misclassifications (NM) and positive misclassifications (PM) to those of experienced radiologists.

Methods: A total of 2,219 annual LDCT scans from the 4ITLR dataset (acquired between 14 December 2022 and 14 January 2025) were independently assessed by both a radiologist and dedicated AI software. In cases of discrepancy, an expert panel served as the reference standard. A case was classified as NM when the final assessment was indeterminate or positive/referral (defined as a volume-doubling time (VDT) of <600 days or the presence of new nodules >30 mm^3) while either the AI or radiologist had initially classified it as negative. Conversely, a case was classified as PM when the final assessment was negative, but the AI or radiologist had categorized it as indeterminate or positive.

Results: AI accounted for 35 NMs (1.6%) and 492 PMs (22.2%), with a negative predictive value (NPV) of 97.8% (95% CI: 97.1-98.4). Of the 35 NM cases, 33 (94.3%) were indeterminate, and 2 (5.7%) required direct referral. Radiologists accounted for 59 NMs (2.7%) and 15 PMs (0.7%), with an NPV of 97.2% (95% CI: 96.5-97.7). Among these, 56 (94.9%) were indeterminate, and 3 (5.1%) required direct referral. Overall, AI classified 27.8% of cases as indeterminate or referral and 72.2% as negative, compared to radiologists with 5.2% and 94.8%, respectively.

Figure 1 shows an indeterminate NM by the AI at the annual follow-up, where it missed a new nodule. However, the nodule disappeared after three months.

Conclusions: AI demonstrated comparable performance to radiologists in independent CT readings within the annual screening round of a LCS trial. AI exhibited a lower rate of NM cases and a similar NPV, indicating its potential to rule out negative cases as a first reader without increasing the risk of missed or delayed diagnoses. While AI produced a higher number of PMs, limiting radiologist review to AI-flagged indeterminate/positive cases could result in a 73.2% reduction in radiologist workload.

P1.04.03 Comorbidities and Social Factors in Lung Cancer Screening Eligibility: Insights From the Colaus and Lc65 Cohorts in Switzerland

L. Gros[1], C. Schneider[2], M-L. Meyer[1], C. Pozzessere[1], C. Bongard[1], Y. Henchoz[2], C. Von Garnier[1], J-L. Bulliard[2], K. Selby[2]
[1]Lausanne University Hospital (CHUV), Lausanne/CH ,[2]Unisanté, Lausanne/CH

Introduction: A key challenge in lung cancer screening is the lack of population-level tobacco use data. In the canton Vaud, Switzerland, a pilot project is evaluating lung cancer screening participation and feasibility. This study aimed to provide an accurate description of the resident population eligible for screening.

Methods: We analyzed self-reported, cross-sectional data from two independent sources to assess screening eligibility (age 50-79 years, ≥20 pack-years smoking, ≤15 years since quitting):

- Lausanne cohort 65+ (Lc65+): 2014 data from a random sample of community-dwelling older adults (65-70 years) in Lausanne, the capital of Canton Vaud.
- CoLaus study: 2021 data from a randomly selected cohort of adults aged 35-75 in Lausanne who were recruited in 2000. Participants aged 50-79 were included.

We then compared eligible and non-eligible participants using descriptive statistics.

Results: Among the 1,678 participants in the Lc65+ cohort, 305 (18.2%) met the screening criteria. Eligible participants included more men (47.5% vs. 42.1% in the non-eligible group), while women were less represented (52.5% vs. 57.9%, p=0.15). Their mean age was 68.0 (SD 1.4) vs. 67.9 (SD 1.4) in the non-eligible group (p=0.8). Eligible participants had higher rates of hypercholesterolemia (40.0% vs. 32.6%, p=0.04), coronary heart disease (9.8% vs. 5.5%, p=0.02), and alcohol abuse (12.8% vs. 4.3%, p<0.001). They also reported more frequent fatigue (p=0.04) and exhibited poorer physical performance, with longer completion times for the 20-meter walk test (15.9s vs. 15.2s, p<0.001) and Up & Go test (10.6s vs. 10.2s, p<0.01). Socioeconomic disparities were evident, with eligible participants having lower incomes (CHF 4,383.0 vs. CHF 5,796.3, p<0.001), higher financial insecurity (17.0% vs. 10.6%, p<0.001), and lower educational attainment (p=0.01). They were also less likely to be Swiss-born (78.4% vs. 84.4%, p=0.03) or to hold a driver's license (50.7% vs. 54.8%, p=0.02). In the CoLaus cohort, 770 of 3,839 participants (20.1%) met the screening criteria. Men were more frequently eligible (49.6% vs. 44% in the non-eligible group), while women were less represented (50.4% vs. 56%, p=0.01). Their mean age was 63.4 (SD 8.2) vs. 62.8 (SD 7.6) in the non-eligible group (p=0.09). Eligible participants reported poorer health (p<0.001) and had higher rates of abdominal obesity (39% vs. 25%, p=0.03). Their lipid profiles were less favorable, with lower HDL (1.50 vs. 1.62 mmol/L, p<0.001), higher triglycerides (1.49 vs. 1.28 mmol/L, p<0.001), and slightly elevated LDL (3.12 vs. 3.20 mmol/L, p=0.04). Fatigue (13.5% vs. 10.1%, p=0.001) and self-care difficulties (7.3% vs. 4.8%, p=0.02) were also more frequent among eligible participants.

Conclusions: Participants in the Lausanne cohorts who were eligible for lung cancer screening had more comorbidities, poorer overall health, and were more socioeconomically disadvantaged compared to non-eligible participants. These disparities underscore the importance of developing tailored lung cancer screening programs that address both medical and social barriers to access.

P1.04.04 Effect of Social Determinants of Health on Lung Cancer Screening Uptake in the U.S

E. Seitz[1], F. Liu[2], C. Wen[3], R. Rao[4], J. Gong[4], S. Prasad[1], H. Xie[5], L. Chiec[6,7], M. Hsu[6,7], A. Dowlati[6,7], Q. Wang[6,7]
[1]Case Western Reserve University School of Medicine, Cleveland/OH/USA ,[2]Department of Population and Quantitative Health Sciences, School of Medicine, Case Western Reserve University, Cleveland/OH/USA ,[3]Quality Operations, Mount Sinai Health System, New York/NY/USA ,[4]Department of Medicine, Case Western Reserve University, Cleveland/OH/USA ,[5]University of Wisconsin-Milwaukee Joseph J Zilber School of Public Health, Milwaukee/WI/USA ,[6]University Hospitals Seidman Cancer Center, Cleveland/OH/USA ,[7]Division of Solid Tumor Oncology, Case Western Reserve University, Cleveland/OH/USA

Introduction: Although individual social determinants of health (SDOH) have been linked to lower lung cancer screening (LCS) rates in the U.S., the impact of cumulative SDOH burden across multiple domains remains unclear. To address this, we used item response theory (IRT) to construct a composite SDOH score that reflects multidimensional social disadvantage. We hypothesized that increased negative social drivers of health are associated with lower rates of LCS.

Methods: This cross-sectional study used combined 2022 and 2023 Behavioral Risk Factor Surveillance System (BRFSS) data. Participants who were eligible for LCS based on United States 2021 Preventive Services Task Force guidelines and had data available for SDOH were included. We included 11 SDOH variables encompassing 4 different domains: 1) social (life satisfaction, feel isolated/lonely, social and emotional support, and stress); 2) economic (employment stability, food insecurity, receipt of SNAP, housing insecurity, and utility service insecurity); 3) environmental (transportation) and 4) healthcare affordability. SDOH scores were generated using unidimensional IRT, with a higher score representing increased negative social drivers of health. Logistic regression models were used to examine the association between SDOH and having an up-to-date LCS, defined as a low dose computed tomography (LDCT) scan within the past 12 months. Stratified analyses by age, sex, and race and ethnicity were performed. All analyses were weighted.

Results: A total of 14,583 (weighted N= 6,809,371) individuals were included. 14.3% received LDCT for lung cancer within the past year. Greater social disadvantage, as indicated by higher SDOH scores, was associated with a numerically lower likelihood of being up to date with LCS (OR: 0.92; 95% CI: 0.84-1.01) but was not statistically significant. After adjusting for age, sex, race, education, geographic region and insurance status, the association did not appear to be statistically significant (OR: 0.99; 95% CI: 0.88-1.11). After stratifying by age, sex, and race and ethnicity, no significant associations were found between SDOH scores and LCS uptake (Table).

Conclusions: In contrast to prior studies that assigned equal weight to individual SDOH indicators, our use of IRT to generate a composite SDOH score did not show a significant association with LCS uptake. This discrepancy highlights the importance of how social disadvantage is measured and suggests that weighting and structure of SDOH domains may influence observed associations. Future research should explore the most appropriate ways to quantify cumulative SDOH burden and validate these approaches across diverse populations to better understand their impact on LCS behaviors.

Summary of associations between social determinants of health score and up-to-date lung cancer screening.

	Odds Ratio	95% Confidence Interval
Overall	0.99	0.88-1.11
Age		
50-64	0.96	0.81-1.14
65-79	1.05	0.90-1.21

Female	0.90	0.76-1.07
Race/ethnicity		
Non-Hispanic White	0.98	0.89-1.11
Non-Hispanic Black	1.01	0.67-1.51
Hispanic	1.01	0.54-1.89
Other	1.11	0.65-1.89

P1.04 SCREENING AND EARLY DETECTION
SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.05 Diminishing Eligibility for Lung Cancer Screening According to Standardized Screening Guidelines

J. Song[1], R. Liu[2,3], S.K. Zhong[3], S. Zhu[3], L. Sakoda[3,4]
[1]Kaiser Permanente Northern California, Santa Clara/CA/USA ,[2]Kaiser Permanente Northern California, San Francisco/CA/USA ,[3]Kaiser Permanente Northern California, Pleasanton/CA/USA ,[4]Kaiser Permanente Bernard J. Tyson School of Medicine, Pasadena/CA/USA

Introduction: In 2021, the United States Preventive Services Task Force (USPSTF) guidelines for lung cancer screening (LCS) expanded the eligibility criteria on age (50-80 years) and smoking history (≥20 pack-years), allowing more racial and ethnic minority individuals and women to be screened. Data are limited on the proportion of individuals diagnosed with lung cancer who could have been screened applying these criteria, especially over time.

Methods: Using linked electronic health record and cancer registry data, we conducted a cross-sectional study of all individuals diagnosed with primary lung cancer from 2014 to 2022 at Kaiser Permanente Northern California, an integrated health care delivery system that serves a socio-demographically diverse population of over 3.6 million U.S. adults. We calculated proportions and 95% confidence intervals of individuals diagnosed with lung cancer who met LCS eligibility in three-year intervals (2014-2016, 2017-2019, 2020-2022), overall and stratified within groups of age, smoking status, race/ethnicity, sex, tumor stage, and neighborhood deprivation index level.

Results: Among 11,736 individuals with lung cancer, the proportion eligible decreased 8.8% overall between 2014-2016 and 2020-2022. In each time interval, the proportion eligible was consistently lower among Asian or Pacific Islander and Hispanic than non-Hispanic white individuals, among women than men, and among individuals living in the least versus most deprived neighborhoods. While the proportion eligible decreased across all groups over time, the absolute decrease was largest among individuals of non-Hispanic Black race (12.4%) and individuals diagnosed with stage I tumors (13.1%).

Conclusions: Our data suggest that the proportion of individuals diagnosed with lung cancer who meet the current USPSTF LCS eligibility criteria at diagnosis is declining over time. This evidence points to a potential growing gap between screening guidelines and the actual population at risk for lung cancer, supporting the continued need to evaluate LCS guidelines and consider other risk factors to ensure effective and equitable early detection of lung cancer.

Diagnosis Year	2014-2016			2017-2019			2020-2022			Absolute Difference from 2014-2016 to 2020-2022 (%)

P1.04.06 AI Performance for Lung Nodule Growth in UK Lung Cancer Screening: Expert Consensus and Histological Validation

B. Jiang[1,2], H.L. Lancaster[2,3], M.P.a. Davies[4], J-W.C. Gratama[5], M. Silva[6], D. Han[2], J. Yi[7], C.M. van der Aalst[1], H.J. de Koning[1], A. Devaraj[8,9], M.A. Heuvelmans[2,10], J.K. Field[4], M. Oudkerk[2,11]
[1]Erasmus Medical Center Rotterdam, Groningen/NL ,[2]Institute for Diagnostic Accuracy, Groningen/NL ,[3]University Medical Center Groningen, Groningen/NL ,[4]University of Liverpool, Liverpool/GB ,[5]Gelre Ziekenhuizen, Apeldoorn/NL ,[6]University of Parma, Parma/IT ,[7]Coreline Soft, Seoul/KR ,[8]Royal Brompton Hospital London, London/GB ,[9]Imperial College, London/GB ,[10]Amsterdam University Medical Centers, Amsterdam/NL ,[11]University of Groningen, Groningen/NL

Introduction: To evaluate the performance of a fully automated artificial intelligence (AI) system in assessing lung nodule growth using volume doubling time (VDT) in follow-up low-dose CT lung cancer screening.

Methods: This retrospective sub-study of the UK Lung Cancer Screening (UKLS) trial included 710 participants with 939 LDCT follow-up scans (3-month: n=361; 12-month: n=578), and 9 diagnosed lung cancers. A commercially available AI system (AVIEW LCS software) automatically performed nodule detection, volumetric measurement, nodule matching, and VDT calculation. For comparison, the same procedure was performed by human readers, which included radiologists from the UKLS trial and two EU radiology-trained readers. According to the NELSON-plus protocol, a case was classified as positive if the largest nodule with solid component ≥100mm3 and VDT ≤400 days, otherwise negative. A blinded European consensus read by a panel of three radiologists with 20 years of experience served as the reference standard, while histological lung cancer outcomes were used as the gold standard.

Results: AI had a discrepancy rate based on final CT-scan outcome (positive/negative) of 8.0% (29/361) at 3-month follow-up and 1.4% (8/578) at annual screening. The negative predictive values (NPV) of AI based on histological results were 99.7% (95%-CI: 98.3-99.9%) at 3 months and 100% (95%-CI: 99.4-100.0%) at 12 months. Among the four lung cancers ≥100 mm^3, AI correctly identified all as having VDT ≤400 days on the earliest follow-up CT (3 months). However, one was classified as negative due to AI's measurement below the 100 mm^3 threshold, resulting in the only protocol-defined false negative. In contrast, human readers missed or delayed referrals in up to 3 out of 4 cases. Of five lung cancers <100 mm^3, one showed no growth (adenocarcinoma in situ), one was slow growth (VDT of 689 days), and the other three were correctly identified by AI as VDT ≤400 days.

Conclusions: AI demonstrated robust performance in fully automated VDT assessment during LDCT follow-up lung cancer screening, accurately identifying all actionable lung cancers ≥100mm^3 and achieving high NPV.

P1.04.07 Projection of the Lung Cancer Screening Eligible Population in Argentina From 2000 to 2050

M.V. Salgado[1], P. Cao[2], J. Jeon[3], R. Mejia[1], R. Meza[4]
[1]Centro de Estudios de Estado y Sociedad, Ciudad de Buenos Aires/AR ,[2]Purdue University, West Lafayette/IN/USA ,[3]University of Michigan, Ann Arbor/MI/USA ,[4]BC Cancer Research Institute, Vancouver/BC/CA

Introduction: Cigarette smoking in Argentina has gradually declined over the past decades; however, 22.2% of the adult population continues to smoke, with lung cancer remaining the leading cause of cancer-related mortality. While many high-income countries recommend lung cancer screening (LCS) for high-risk individuals, Argentina's National Ministry of Health has yet to issue a recommendation. Here, we project the annual percentage and number of individuals eligible for LCS in Argentina from 2000 to 2050 to inform policy and clinical decisions.

Methods: We developed an Argentinean version of the Cancer Intervention and Surveillance Modeling Network (CISNET) Smoking History Generator (SHG), a microsimulation model that generates cohort-specific smoking histories by age and gender. Argentina's SHG was parameterized with smoking data from nationally representative surveys, population projections from the United Nations, and mortality data from the Cancer Prevention Study II. Using the simulated population by the Argentinean SHG, we estimated the number of LCS-eligible individuals in the country for the period 2000-2050 under the US Preventive Services Task Force criteria (adults aged 50-80 years who have a 20 pack-year or more smoking history and currently smoke or have quit within the past 15 years).

Results: The Argentinean SHG reproduces the observed smoking prevalence in Argentina. The number of LCS-eligible individuals is projected to rise from 1 million people in 2000 to 1.6 million in 2018, remain stable until 2036, and then decline to 1.3 million by 2050. As the population grows and smoking prevalence continues to decline, the proportion of LCS-eligible individuals aged 50-80 is expected to nearly halve, declining from 15.1% in 2018 (the peak for eligibility) to 7.8% by 2050. Similar trends are observed in both men and women (Figure 1).

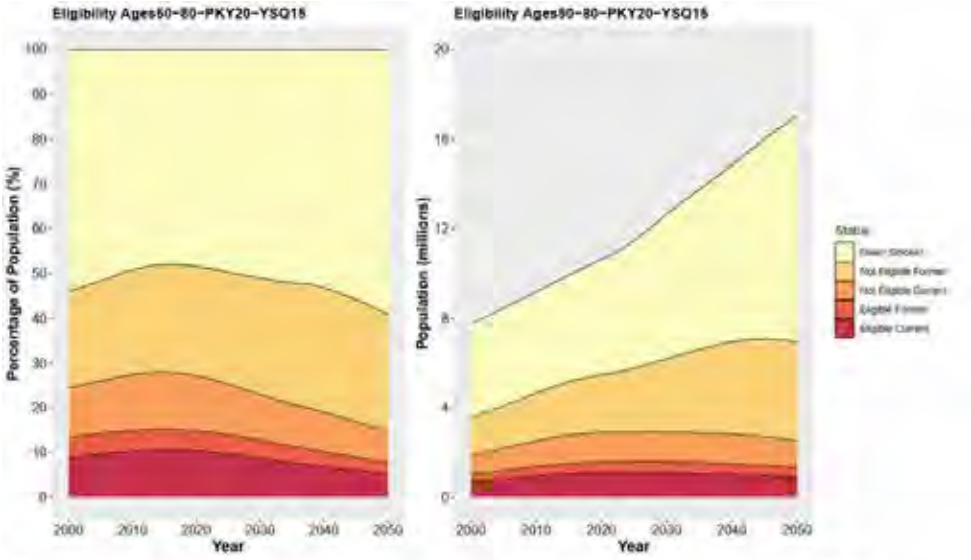

Figure 1. Projected LCS-eligible population from 2000-2050 with age eligibility 50-80. **Left:** Percentage of adults aged 50-80 by eligibility and smoking status (stacked areas). The bottom two areas represent the proportion of LCS-eligible individuals (current and former smokers). **Right:** Projected number of individuals aged 50-80 by eligibility and smoking status (stacked areas). The bottom two areas represent the number of LCS-eligible individuals (current and former smokers).
PKY: pack-years; YSQ: years since quitting; LCS: lung cancer screening.

Conclusions: Although the number of individuals eligible for LCS in Argentina is projected to decline, more than one million people will still qualify by mid-century, underscoring the need for a national LCS program to reduce lung cancer burdens and associated costs. The eligible population for lung cancer screening under current criteria is expected to decline over time, underscoring the urgency of implementing programs in the near future to maximize public health impact.

Acknowledgment. This work was supported by an IASLC Young Investigator Grant awarded to Dr. Salgado.

P1.04.08 Program Guidelines for Australia'S National Lung Cancer Screening Program: A Robust and Consultative Development Approach

N. Rankin[1], R. Zosel[1], L. Whop[2], R. Maddox[2], C. Nightingale[1], G. Bartlett[1], R. Lantin[1], A. McWilliams[3], J. Emery[1], F. Brims[4], M. Brooke[5], M. Siemienowicz[6], D. Pascoe[7], S. Melsom[8], M. Itel[5], A. Fidler[5], A. Brown[1], A. Diaz[2], S. McDermott[9], K. Anderson[10], L. Liu[10], V. Milch[10], D. Keefe[10]
[1]University of Melbourne, Melbourne/AU ,[2]Australian National University, Canberra/AU ,[3]Fiona Stanley Hospital, Perth/AU ,[4]Curtin University, Perth/AU ,[5]Lung Foundation Australia, Brisbane/AU ,[6]Northern Imaging Victoria, Melbourne/AU ,[7]Royal Melbourne Hospital, Melbourne/AU ,[8]Perth Radiological Clinic, Perth/AU ,[9]National Aboriginal Community Controlled Health Organisation, Canberra/AU ,[10]Cancer Australia, Sydney/AU

Introduction: The Australian National Lung Cancer Screening Program (hereafter 'Program') will commence from July 2025. The Program is the first new cancer screening program in Australia in 20 years. The Program aims to improve health outcomes for Australians by detecting lung cancer early and reducing deaths from lung cancer. It represents a significant investment across healthcare sectors, including extensive Aboriginal and Torres Strait Islander (First peoples of Australia) engagement as a mandatory component, reflecting the disproportionate burden of lung cancer among Aboriginal and Torres Strait Islander communities. Cancer Australia commissioned The University of Melbourne, The Australian National University and Lung Foundation Australia, to develop Program Guidelines. This presentation summarises the Guideline content and highlights an agile approach to development.

Methods: The purpose of the Guidelines was to create best practice recommendations to help healthcare providers and participants navigate the Program. A project plan was developed. A desktop review of international guidelines and protocols was undertaken and a robust consultation approach to engage key stakeholders was outlined. Stakeholders included Aboriginal and Torres Strait Islander health professionals and community members, clinicians, consumers, and policy and program advisors. Shared decision-making materials for Aboriginal and Torres Strait Islander communities were developed concurrently. A multidisciplinary working group was formed to provide expert clinical and consumer input throughout development. The project team conducted extensive interviews, focus groups, and workshops with stakeholders to refine content and identify service design issues. Draft content addressed both the breadth and depth of lung cancer screening topics. Draft content was iteratively shared with policymakers. Public consultation commenced in late November 2024 with a final draft being made available for whole of community review. The Guidelines were finalised, endorsed and released in April 2025.

Results: More than 170 stakeholders participated in consultation activities from across all Australian states and territories, geographic areas, and healthcare settings. The Guidelines include specific evidence-based recommendations, practice points, and content summaries to guide implementation. They are tailored to the unique Australian context, addressing issues of equity, cultural safety, smoking cessation, and stigma. The Screening and Assessment pathway covers topics such as promotion and awareness, eligibility, program entry, enrolment and shared decision-making, smoking cessation, delivery of the low-dose CT scan, assessment and reporting, results management, and screening reminders. Low-dose CT scans will be reported using the Program's Nodule Management Protocol. The intersection with the Australian National Cancer Screening Register for results reporting was developed concurrently by clinical experts and policymakers. The Guidelines detail healthcare providers' roles and responsibilities and include links to program-specific resources designed to inform community members and encourage shared decision-making. During public consultation, 96% of respondents agreed that the Guidelines were fit for purpose.

Conclusions: The Program Guidelines will support the delivery of a safe, effective, and high-quality lung cancer screening program for the Australian community. Engaging stakeholders through inclusive approaches is essential to Guideline development. Collaborative efforts will help build awareness and trust in the Program, ensuring its successful and equitable implementation. The robust and thorough development process could be adapted by other jurisdictions.

P1.04.09 Size Distribution and Short-Term Progression of New Nodules From the 4ITLR Lung Cancer Screening Trial

D. Han[1], B. Jiang[1,2], A. Walstra[1], M. Heuvelmans[1,3,4], J-W. Gratama[5], M. Silva[6], C. van der Aalst[2], H. de Koning[2], M. Oudkerk[1,7]
[1]Institute for Diagnostic Accuracy, Groningen/NL ,[2]Erasmus Medical Center, Rotterdam/NL ,[3]Amsterdam Medical Center, Amsterdam/NL ,[4]University Medical Center Groningen, Groningen/NL ,[5]Gelre ziekenhuizen, Apeldoorn/NL ,[6]University of Parma, Parma/IT ,[7]University of Groningen, Groningen/NL

Introduction: Lung cancer screening (LCS) with low-dose CT has been shown to reduce mortality in high-risk individuals. Previous studies indicate that new pulmonary nodules detected during follow-up LCS rounds have a higher likelihood of malignancy relative to their size compared to the nodules found in the baseline screening. However, evidence on the optimal management of new nodules in LCS remains limited. This study evaluates new nodules detected during the first annual LCS round in the European 4-IN-THE-LUNG-RUN (4ITLR) trial, and their progression over a three-month period.

Methods: Chest LDCTs from 2,219 annual LCS screening participants of the 4ITLR trial (acquired between 14 December 2022 and 14 January 2025) were included in this study. Each scan was independently evaluated by a radiologist and an AI system. In cases of discrepancy, an expert panel served as the reference standard. New nodules, either solid or part-solid with a solid component of ≥30mm3 that were identified as the reference nodule based on size were selected for analysis. Percentage of participants with new nodules, nodule size category, as well as 3-month progression of new nodules were evaluated.

Results: A total of 90 out of 2,219 participants (4.1%) were identified with a new nodule ≥30mm^3. Of the detected new nodules, 52 (2.3%) were 30-200mm^3, and 38 (1.7%) were ≥200mm^3. Of the cohort with new nodules, 65 of the participants underwent a 3-month repeat CT. Among them, 9 (0.4%) showed growth, 14 (0.6%) remained stable, 6 (0.3%) were in the process of resolving, and 36 (1.6%) had resolved.

Conclusions: In an annual LCS round, 4.1% of participants were found to have new pulmonary nodules, with around half resolving after a 3-month repeat CT. These findings are consistent with previous results from the NELSON trial.

Keywords: Lung cancer screening, New nodules, Computed tomography

P1.04.10 Lung Cancer Screening Completion Rates as Predicted by Social Deprivation

R.M. Williams, A. Sangraula, S. Melvin, K.L. Taylor, G. Luta
Georgetown University Medical Center, Washington/DC/USA

Introduction: Globally, there is a strong association between lower socioeconomic status (SES) and higher incidence of lung cancer, later stage diagnosis, and poorer overall survival. In the United States (U.S.), lung cancer screening (LCS) via low-dose computed tomography is recommended for those at high risk, but LCS uptake is low (16-20%) overall, and is lower among those with less income. We evaluated social deprivation as a predictor of LCS completion rates among primary care patients seen in a large health system.

Methods: Utilizing electronic health record data from MedStar Health, an integrated delivery network health system in the Mid-Atlantic U.S., we analyzed LCS completion rates in the past 12 months among patients who received a LCS referral (N=829) between September 2022 - August 2023, across 51 primary care clinics. We used the validated 2019 Social Deprivation Index (SDI), with a scale from 1 to 100, with a higher score reflecting more social deprivation and worse SES status. To assess social deprivation as a predictor of LCS completion, SDI was coded as a categorical variable (1-24, 25-49, 50-74, 75-100).

Results: The mean age was 66 (SD=7), 36% were Black or African American, and 65% were currently smoking. About 26% of the sample were in the lowest category of social deprivation, 21% in the 25-49 category, 22% in the 50-74 category, and 31% in the highest category (75-100). Among referred patients, the overall LCS completion rate was 24%. Using a logistic regression model with generalized estimating equations (GEE), SDI predicted LCS completion, controlling for sex, race, smoking status, insurance, and clinic type (hospital- vs. community-based) (Table 1). Compared to patients with the lowest SDI (1-24), patients with the highest SDI (75-100) had significantly lower odds of completed LCS (OR=0.58, 95% CI: 0.36-0.94).

Conclusions: In a large, socioeconomically diverse health system, our findings revealed that higher social deprivation was associated with lower LCS completion among patients referred to screening. One study limitation is the use of a single measure of social deprivation. While a LCS referral is necessary, additional strategies are needed to increase successful completion of LCS among lower socioeconomic groups.

P1.04.11 New Nodule Lung Cancer in the UK Lung Cancer Screening Trial: Characteristics and Comparison With NELSON

B. Jiang[1,2], H.L. Lancaster[2,3], M.P.a. Davies[4], D. Han[2], J-W.C. Gratama[5], M. Silva[6], C.M. van der Aalst[1], H.J. de Koning[1], A. Devaraj[7,8], M.A. Heuvelmans[2,9], J.K. Field[4], M. Oudkerk[2,10]
[1]Erasmus Medical Center Rotterdam, Rotterdam/NL ,[2]Institute for Diagnostic Accuracy, Groningen/NL ,[3]University Medical Center Groningen, Groningen/NL ,[4]University of Liverpool, Liverpool/GB ,[5]Gelre Ziekenhuizen, Apeldoorn/NL ,[6]University of Parma, Parma/IT ,[7]Royal Brompton Hospital London, London/GB ,[8]Imperial College, London/GB ,[9]Amsterdam University Medical Centers, Amsterdam/NL ,[10]University of Groningen, Groningen/NL

Introduction: New nodules detected during lung cancer screening follow-up rounds differ in malignancy risk from baseline nodules. We aimed to characterize new nodules and associated lung cancers in the UK Lung Cancer Screening Trial (UKLS) and compare these findings with results from the NELSON trial.

Methods: We included 875 participants of the multicenter randomized-controlled UKLS trial ("Wald Single-Screen" design, registration number: ISRCTN78513845) that underwent follow-up low-dose CT screening. Non-calcified nodules containing solid components that were registered by the UKLS radiologists as new or smaller than 15 mm3 (study detection limit) at previous screens were defined as new nodules. Nodule volume was generated semiautomatically by software. Lung cancer diagnosis was based on histology, and benignity was based on histology or stable size for at least 2 years. UKLS findings were compared with published results from the NELSON trial.

Results: UKLS radiologists registered 233 new solid nodules in 142 participants who received a follow-up CT. Lung cancer was diagnosed in 5 (4%) of participants with new solid nodules, representing 2% (5/233) of all new solid nodules. Four (80%) lung cancers were diagnosed at stage I. The probability of malignancy was 0% (0/135) in participants with new nodules detected during repeat short-term follow-up (3/6/9 months) and 5% (5/98) in those with nodules detected at annual follow-up (12 months). Lung cancer probability was stratified by nodule volume at first detection: 0% (0/72) for nodules <30 mm^3, 2% (3/129) for nodules between 30-200 mm^3, and 6% (2/32) for nodules ≥200 mm^3. This volume-dependent risk distribution is consistent with the results reported in the NELSON trial.

Conclusions: UKLS results confirm key findings from NELSON, showing that new solid nodules are detected in 4% of screened individuals and that malignancy risk increases with volume. The thresholds of 30-200 mm^3 remain valid for risk stratification of new nodules in lung cancer screening.

P1.04.12 Smoking Duration Lung Screening Criteria (Potter Criteria) Captures More Underrepresented Individuals at Risk for Lung Cancer

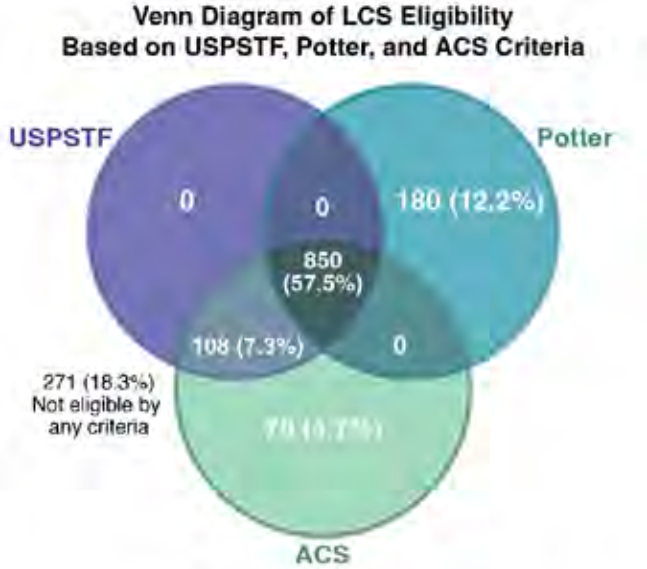
T. Hill[1], A.L. Potter[2], H. Ouyang[1], L. Liu[1], A. Chang[2], L. Sequist[2], C-F.J. Yang[2], K. Kovitz[1], R. Nguyen[1], F. Weinberg[1], M.M. Pasquinelli[1]
[1]University of Illinois Chicago, Chicago/IL/USA ,[2]Mass General Brigham, Boston/MA/USA

Introduction: Current U.S. Preventative Services Task Force (USPSTF) lung cancer screening (LCS) eligibility criteria exclude many high-risk individuals, especially those from racial and ethnic minority groups. Recently proposed alternatives include the Potter criteria (which replace the 20-pack-year threshold in the USPSTF criteria with a 20-year duration threshold), and American Cancer Society (ACS) criteria (which remove the 15-years-quit requirement). We compared the performance of the USPSTF, Potter, and ACS criteria among individuals diagnosed with lung cancer (LC) at an academic medical center serving a predominantly minority population in Chicago.

Methods: We evaluated LCS eligibility under the USPSTF, Potter, and ACS criteria using data from 1479 individuals with LC diagnosed at The University of Illinois Hospital & Health Sciences System from 2010-2024. Patients without a history of tobacco use were excluded. A multinomial model evaluated race and gender imbalances in eligibility.

Results: Of the 1479 patients, 958 (64.8%) met USPSTF criteria, 1030 (69.6%) met Potter, and 1028 (69.5%) met ACS; 850 (57.5%) individuals met all three criteria (Fig 1). Compared to USPSTF, an additional 180 (12.2%) individuals would have been screen-eligible under Potter and 70 (4.7%) under ACS. Relative to those who met all three criteria, the 180 added under Potter were significantly more likely to be Black (odds' ratio [OR]: 4.77, 95% CI: 2.59-8.79) or Hispanic (OR: 4.77, 95% CI: 2.11-10.8) and the 70 added under ACS were less likely to be Black (OR: 0.47, 95% CI: 0.27-0.81) compared to White patients. Of 108 (7.3%) individuals qualifying for screening under USPSTF but not Potter (due to <20 years tobacco use), most were White, used tobacco with high daily intensity (median: 39 cig/day), and for shorter durations (median: 15 years). 271 (18.3%) individuals met none of the screening criteria, of which 59% were ineligible due to age (<50 or >80). Compared to those meeting all three criteria, those meeting none were more likely to be female or Hispanic.

Conclusions: In this analysis of 1479 patients with LC and tobacco use history, we found that only 64.8% met USPSTF criteria. The Potter criteria identified an additional 12.2% of individuals, most of whom were Black or Hispanic. These data further support that including a tobacco use duration threshold in LCS guidelines can reduce racial and ethnic disparities in screening eligibility and improve equity in opportunities for early lung cancer detection.



Criteria	N (%)	Non-Hispanic Black	Non-Hispanic White	Hispanic	Other/Mixed Race	Unknown
USPSTF & ACS & Potter	850 (57.5)	517	217	58	37	21
USPSTF & ACS	108 (7.3)	51	38	8	6	5
ACS only	70 (4.7)	30	27	6	7	0
Potter only	180 (12.2)	138	12	15	5	10
No criteria met	271(18.3)	142	57	39	20	7

P1.04.13 The Impact of Reconstruction Kernel and Hounsfield Unit Threshold on Emphysema Quantification From Lung Cancer Screening Data

I. Visser[1,2], H. Liu[2,3], D. Han[2], M. Oudkerk[1,2]
[1]University of Groningen, Groningen/NL ,[2]Institute for DiagNostic Accuracy, Groningen/NL ,[3]Erasmus Medical Center, Rotterdam/NL

Introduction: Emphysema is a non-reversible disease which currently has no cure. Diagnosing early-stage emphysema using computed tomography (CT) scans remains a challenge. A potential tool is quantitative CT, via the measurement of the lung Low-Attenuation Area percentage (LAA%). However, different parameters could influence this quantification, including the reconstruction kernel and HU threshold. The aim of this study is therefore to investigate the effect of different kernel-HU threshold combinations on the lung LAA% from CT images calculated by AI software.

Methods: 352 lung CT cases were obtained from the Netherlands-China-Big-3 study.The LAA% was calculated for cases by Aview (Coreline Soft, version 42) using different kernels (B30f, D45f and B80f) at different HU thresholds (-940, -950, -960 and -970 HU). Descriptive statistics were calculated for age and sex. Cases were also categorized as emphysema being present (LAA% ≥6%) or not (LAA% <6%). Friedman and Cochran's tests were performed to establish whether there were any significant differences between the LAA% and emphysema characterisation, respectively, across all groups. Individual group comparisons were performed using the Wilcoxon signed rank test and the McNemar test for LAA% and emphysema, respectively, using the Holm multiple testing correction.

Results: The participants have a median age of 62 years (IQR: 8.25), with 51.7% being female. There is a significant difference in LAA% across all kernel-HU thresholds (p<0.001). Kernel D45f produces a higher LAA% than kernels B30f and B80f for all thresholds (Figure 1). Out of 66 group comparisons, 62 are significantly different; all comparisons except for the LAA% for kernel B30f and B80f at the same HU threshold. Furthermore, emphysema categorisation is significantly different when comparing all kernel-HU thresholds together (p<0.001). Among the 12 kernel-HU threshold groups, most patients are categorised as having emphysema for kernel D45f at -940 and -950 HU, while for other groups the majority of patients are categorised as not having emphysema. Out of 66 group comparisons, 54 are significantly different. Kernel B30f and D80f are not significantly different at the same HU threshold. Besides, there is no significant difference between -940-B80f and -970-D45f.

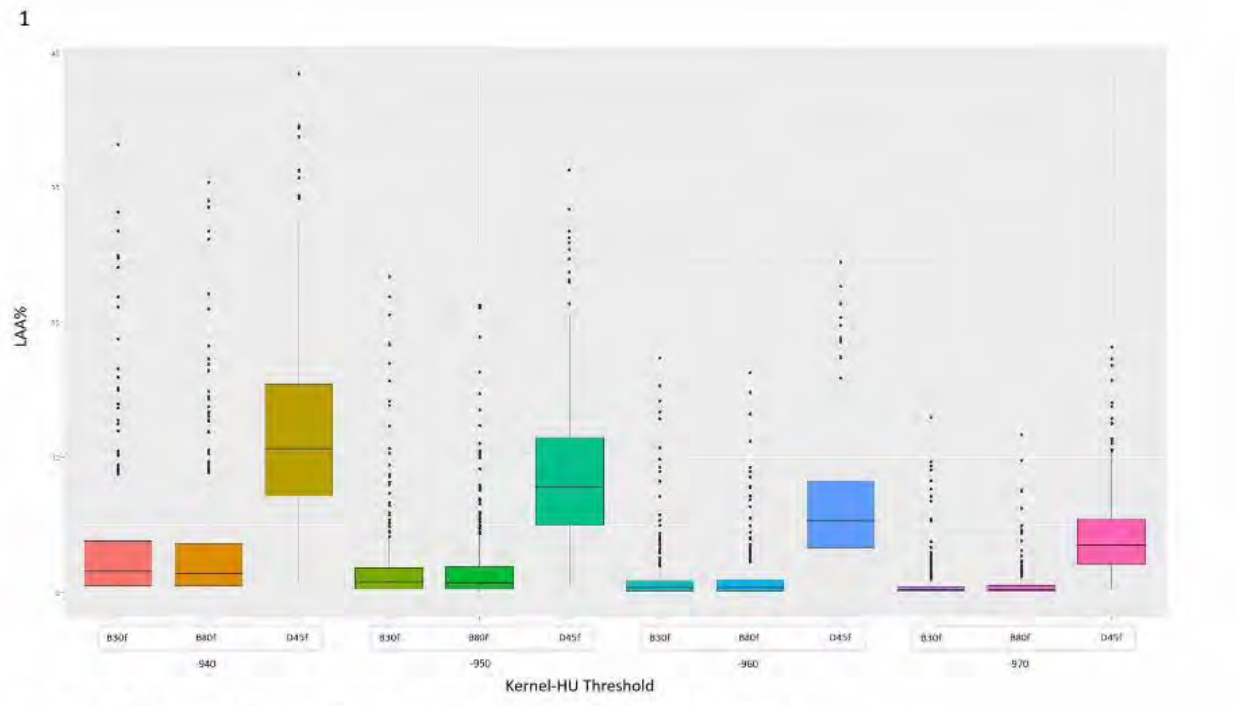

Figure 1: A boxplot of the distribution of LAA% per kernel-HU threshold combination

Conclusions: To conclude, LAA% is influenced by kernel and HU threshold. Notably, the D45f kernel, at higher HU thresholds, categorizes more patients as having emphysemas, which may have implications for diagnosis.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.14 Age, Risk Thresholds and Cost-Effectiveness: Evaluating Lung Cancer Screening Using the PLCOm2012 Model

M. Sikarwar[1], A. Kuhlmann[2,3]
[1]Institute for Medical Epidemiology, Biometry and Informatics, Halle(Saale)/DE ,[2]Institute for Social Medicine and Epidemiology, University of Lübeck, Lübeck/DE ,[3]Working Group Health Economics, Martin Luther University Halle-Wittenberg, Halle(Saale)/DE

Introduction: Lung cancer (LC) is one of the leading causes of cancer related mortality worldwide. However, it has been observed that LC screening using Low dose computed tomography (LDCT) reduces LC mortality. Risk based LC screening which calculates screening eligibility based on individual risk, has shown to improve the sensitivity and specificity when compared with 2013 United States preventive services task force criteria. This study evaluates the effects of PLCOm2012 model with different risk thresholds (0.5-3%) across 6 age groups (55-70, 55-75, 55-80, 50-70, 50-75, 50-80) on screening outcomes- prevented LC deaths, Life years gained (LYG), prevented LC deaths per 1000 screens, LYG per 1000 screens and incremental cost effectiveness ratio (ICER) for efficient strategies in a German population-based setting in a 5-year screening program.

Methods: We used our modular microsimulation model to simulate individual life histories, mapping the development of lung cancer and its progression from first malignant cell to eventual LC death. Smoking behavior related data was obtained from the German Health Update (GEDA) survey (years 2009-2012) and demographic structure (2012) was obtained from the German statistical office. Results for PLCOm2012 risk thresholds (0.5-3%) for all 6 age groups were calculated and compared.

Results: At lower risk thresholds (0.5-1%), prevented LC deaths ranged from 25,588 to 43,421 deaths and LYG ranged from 378,784 to 593,927 years across all age groups. At higher risk thresholds (2.5-3%), prevented LC deaths ranged from 10,221 to 22,351 deaths and LYG ranged from 134,212 to 255,197 years across all age groups. At lower risk thresholds (0.5-1%), prevented LC deaths per 1000 screens ranged from 0.9 to 1.4 deaths and LYG per 1000 screens ranged from 13 to 21 years across all age groups. At higher risk thresholds (2.5-3%), prevented LC deaths per 1000 screens ranged from 2.3 to 2.8 deaths and LYG per 1000 screens 26 to 37 years across all age groups. At lower risk thresholds (0.5-1%), 55-70 years old (yo) age group had higher LYG per 1000 screens and 55-75 yo age group had higher prevented LC deaths per 1000 screens as compared to other age groups. At higher risk thresholds (2.5-3%), both 55-70 yo and 50-70 yo age groups had higher LYG per 1000 screens and higher prevented LC deaths per 1000 screens as compared to other age groups. Risk thresholds (0.6-3%) showed ICER lower than 50,000 euros/LYG (generally assumed ICER threshold for Germany). It ranged from 6,599 to 47,198 euros/LYG. ICER at 0.5% risk threshold was 54,680 euros/LYG.

Conclusions: While higher risk thresholds (2.5-3%) showed higher prevented LC deaths per 1000 screens and LYG per 1000 screens but they also excluded a lot of cases that could have been identified at lower risk thresholds. ICER results suggest that lower risk thresholds might still be cost effective. This study advocates for a tailored, risk-based screening policies to maximize public health benefits while being cost effective.

P1.04.15 Lung Cancer Screening in Switzerland: Baseline Results From the Vaud Pilot Project

C. Bongard[1], A. Cobuccio[1], M. Faucher[1], M. Lugon[1], C. Schneider[2], J-L. Bulliard[2], D. Rotzinger[1], K. Selby[2], C. Pozzessere[1], C. von Garnier[1]
[1]Lausanne University Hospital, Lausanne/CH ,[2]Center for Primary Care and Public Health (Unisanté), Lausanne/CH

Introduction: Lung cancer screening (LCS) with low-dose CT (LDCT) effectively reduces lung cancer mortality. The Vaud LCS pilot project is a four-year project mandated by cantonal health authorities to assess the feasibility of implementing a population-based, organized LCS program. We report insights into the implementation and preliminary clinical results of this pilot project after the baseline LDCT.

Methods: The pilot project enrolled high-risk subjects based on USPSTF 2021 criteria for LCS (adults aged 50-79 years, ?20 pack-year smoking history, cessation ?15 years). Data were collected from November 2023 to December 2024. Recruitment was conducted by mailing 8000 invitations to a random sample of individuals aged 50-79 and through direct inclusion of patients by their physicians across Canton Vaud. During the inclusion visit, participants underwent a guided interview focused on respiratory health, followed by post-bronchodilation spirometry and baseline LDCT. An optional smoking cessation consultation (SCC) was proposed to active smokers. Nodules were evaluated using LungRADS v2022 and NELSON+ classifications. A dedicated multidisciplinary nodule review board (MNRB) integrated clinical and radiological data with the Brock model for risk stratification to refine nodule assessment of indeterminate and positive LDCT results (Lung-RADS/NELSON+ 3 or more; Lung-RADS 0; mediastinal and/or hilar adenopathy) and decide for annual screening in case of downstaging, 3-month follow-up for those assessed indeterminate or further investigations for positive findings.

Results: The mail recruitment achieved a 35% response rate of the estimated eligible population. From the scheduled baseline appointments, we experienced a 3.2% of no-show rate, ultimately including 1,000 participants. 70% were active smokers, of which 54% attending SCC. Baseline LDCT results showed 83.8% negative, 14.6% indeterminate, and 1.6% positive findings. MNRB increased the number of negative LDCT to 87.3%, reducing indeterminate and positive results to 11.2% and 1.5%, respectively. Of the 15 positive cases, 7 were histologically-confirmed lung cancers.

Conclusions: Our baseline preliminary results overall align with published data and participation rates. Incorporating a dedicated MNRB to review indeterminate and positive LCS results may enable a more personalized nodule assessment and management, while driving continuous quality improvement to control false-positive rates. Consolidated results through a comprehensive evaluation of the performance of this pilot program are however required upon completion of the four annual LDCT screening rounds.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.16 Real-World Outcomes of Lung Cancer Screening and High-Risk Lung-RADS 4 Nodules at VA Northern California Health Care System

C.D. Ochoa[1,2], A. Guru[1], S. Zanfardino[1], B. Guan[1], E.R. Thomas[1], D. Liu[3], S. Chen[3], T. Li[1,3]
[1]Sacramento VA Medical Center, Mather/CA/USA ,[2]University of California, Davis, Sacramento, CA/CA/USA ,[3]University of California, Davis, Sacramento/CA/USA

Introduction: Supported by the Lung Precision Oncology Program, the hybrid lung cancer screening (LCS) program at VANCHCS was expanded in 2021. As of March 1, 2025, 5,283 of 6,509 eligible Veterans (81.2%) have been assessed, with 4,479 (89%) enrolled. Some patients were later excluded due to co-morbidities, new cancer diagnoses, or death. The Lung Imaging Reporting and Data System (Lung-RADS) guides clinical decision-making based on radiographic risk. Lung-RADS 4 (LR4) indicates high-risk nodules requiring prompt follow-up due to elevated malignancy risk. Evaluating follow-up, diagnostic yield, and staging in LR4 nodules offers insight into program effectiveness and patient outcomes.

Objective: To evaluate diagnostic outcomes, pathology-confirmed malignancies, and cancer staging in patients with LR4 nodules in a single-institution LCS program.

Methods: All LCS data were tracked using VA's LCS national dashboard. We analyzed patients with high-risk LR4 data, including demographics, biopsy dates and modalities, pathology results, time from LR4 scan to biopsy, AJCC 8th edition staging, and first specialty consultation.

Results: Since its inception, the program has performed 10,155 low-dose CT (LDCT) scans and is actively tracking 3,946 veterans, maintaining 94.1% adherence to screening guidelines. The program's diagnostic yield for lung cancer was 3.3%. We identified 122 patients diagnosed with cancer in our LCS program. 40 were excluded as they received subsequent care outside the VA. The final analysis included 82 veterans with LR4 findings on LDCT between 2021 and 2024. The mean age at diagnosis was 70.3 years (range 54-79). The median interval from LR4 detection to biopsy was 50.5 days (range 6-342), reflecting wide variability. Final pathology reports are available in 79.3% of cases, with malignancy confirmed in most biopsied nodules. Adenocarcinoma was the most common diagnosis (n=32), followed by squamous cell carcinoma (SCC, n=21), other non-small cell lung cancers (NSCLC, n=14), and small cell lung cancer (n=6). Staging data showed a meaningful spread across early and advanced disease. 39 patients were diagnosed at stage I, 6 at stage II, and 10 at stage IIIA or IIB, supporting the program's role in early detection. However, 5 presented at stage IIIC and 6 at stage IV, emphasizing the need for timely evaluation and care escalation. All patients received prompt specialty referrals to radiation oncology, thoracic surgery, or medical oncology based on disease severity and operability

Conclusions: The LR4 designation reliably identifies high-risk nodules with a high malignancy rate and a predominance of adenocarcinoma and SCC, aligning with national trends. The fact that 67% of cancers were diagnosed at stage I, II, and IIIA or IIIB underscores the effectiveness of LCS in enabling timely, potentially curative interventions. Nonetheless, opportunities remain to improve early detection, particularly by addressing delays in biopsy and inconsistencies in documentation. Standardizing workflows, ensuring structured follow-up, improving patient navigation, and strengthening multidisciplinary coordination are essential next steps. Ongoing tracking of LR4 outcomes and real-time data monitoring will be critical to maintaining high-quality care and maximizing the impact of early lung cancer detection.

P1.04 SCREENING AND EARLY DETECTION
SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.17 Poor Utilization of Lung Cancer Screening Among Cancer Survivors in the United States

A.P. Chidi, K.S. Tan, P. Adusumilli, M. Bott, K. Gray, J. Huang, J. Isbell, D. Molena, B. Park, G. Rocco, V. Rusch, S. Sihag, D.R. Jones, F. Gany
Memorial Sloan Kettering Cancer Center, New York/NY/USA

Introduction: Although lung cancer screening can significantly reduce lung cancer-related mortality, fewer than 20% of eligible patients are screened in the United States each year. Survivors of other cancers who meet lung cancer screening eligibility criteria are at particularly high risk but there are limited national data regarding screening habits among these patients.

Methods: We conducted a cross-sectional analysis of data from the 2022 Behavioral Risk Factor Surveillance System. We included respondents aged 50-80 who reported a 20 pack-year or greater smoking history, a history of prior cancer diagnosis, and smoking within the past 15 years. Respondents with prior lung cancer or ongoing cancer treatment were excluded. Among survivors eligible for lung cancer screening, we assessed sociodemographic and behavioral factors associated with lung cancer screening with low-dose CT within the past year. For survivors meeting United States Preventive Services Task Force criteria for mammography or colonoscopy as well as lung cancer screening, we assessed the comparative utilization of each screening exam. These analyses excluded survivors of breast or colon cancer. Two-tailed p-values <0.05 were statistically significant.

Results: We identified 413,640 cancer survivors who were eligible for lung cancer screening: mean age 66 (IQR 65, 67), 48% women. Overall, 33% of eligible cancer survivors had a screening CT scan. Men were significantly more likely to be screened than women (40% vs. 31%, p=0.007). There were no significant differences in screening based on race, education, income, insurance, or current vs. former smoking status. Of eligible survivors, 17% were United States Veterans who were significantly more likely to undergo lung cancer screening than non-Veterans (50% vs. 29%, p=0.001). 57% of eligible survivors were current smokers; of these, 44% reported a smoking cessation attempt within the past year. Attempted smoking cessation was not associated with lung cancer screening (p=0.27). Of the 185,816 eligible female survivors without prior breast cancer, 71% reported up-to-date mammography. In the same cohort, only 25% of respondents underwent lung cancer screening. Receipt of mammography was not associated with lung cancer screening (p=0.48). Of the 353,177 eligible survivors without prior colon cancer, 84% reported guideline-concordant colon cancer screening. In the same cohort, 31% of patients underwent lung cancer screening. Guideline-concordant colon cancer screening was not associated with lung cancer screening (p=0.48).

Conclusions: Lung cancer screening is poorly utilized among eligible cancer survivors in the United States. By contrast, there is a high prevalence of guideline-concordant breast and colorectal cancer screening in the same patient population. These data reflect a willingness among cancer survivors to undergo further cancer surveillance but suggest gaps in patient and provider education and outreach. Cancer survivors often receive specialized, long-term follow up care in survivorship programs, presenting a unique opportunity for improved population-based screening interventions for this high-risk patient population.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.18 Diagnosis of Sub-Cm Lung Nodules With Deep Learning Segmentation and Radiomics-Based Machine Learning Classifiers

I. Janzen[1], R. Abraham[2], S. Khattra[3], R. Myers[3], R. Yuan[3], S. Lam[3], C. MacAulay[3]
[1]BC Cancer, Vancouver/BC/CA ,[2]BC Genome Science Center, Vancouver/BC/CA ,[3]BC Cancer Research Institute, Vancouver/BC/CA

Introduction: Lung cancer remains the leading cause of cancer deaths in Canada. Detection, diagnosis, and treatment of early-stage lung cancers via Low-Dose Computed Tomography (LDCT) screening programs have been shown to substantially reduce lung cancer mortality. Developing computer-aided diagnosis (CADx) tools to assist physicians in identifying potential cancerous lung nodules during screening studies are especially desirable for notoriously difficult-to-classify nodules (i.e., sub-cm, <10mm solid component diameter, GGOs) as these cases tend to have relatively small amounts of pixel-based information available to them. Compounded by the large number of small objects often detected during screening programs, the implementation of CADx tools for cost-effective screening prediction is in high demand. We posit that one can train a pipeline consisting of deep learning and machine learning models to segment and classify sub-cm nodules as malignant or benign with radiomic features to greatly speed up nodule assessment speeds and allow for the implementation of early cancer treatment for protocols during baseline scans.

Methods: The discovery dataset for this study draws nodules (N=6944, n=136 cancers) from the Pan Canadian Screening Study (PanCan) which provided LDCT lung volumes. Each nodule was axially segmented using a self-attention UNet, and then three discrete masks that represent the nodule core, core plus edge parenchymal tissues, and the peritumoral region surrounding the nodule were generated. Radiomic features are calculated from each mask and a sequential forward feature selection was applied to identify a highly discriminating radiomic signature. A logistic regression (LR) model was trained from this radiomic signature in a binary classification task of predicting cancer versus benign nodules. In addition, an external validation cohort draws sub-cm nodules (N=2943, n=36 cancers) from the more recent International Lung Screening Trial (ILST) to determine the radiomic signature's generalizability and medical utility.

Results: ROC analysis was performed on the 5-fold cross validated LR model that resulted in an AUC=0.970 [Sen: 0.911, Spec: 0.951]. This radiomics-based CADx model was able to identify 12 cancerous sub-cm nodules at baseline that would have not received interventional treatment as these nodules held a Brock model score <=5%. In addition, the model showed an ability to predict cancerous vs benign nodules up-to 24 months before clinical confirmation of malignancy. Additional analysis will be performed on the external validation cohort in the immediate future.

Conclusions: This study suggests that our pipeline consisting of a deep learning-based segmentation method to machine learning model, trained on a highly discriminating baseline LDCT radiomic signature, can identify sub-cm diameter cancerous nodules up to 24 months before clinical confirmation of malignancy. Pending verification of this model on the external validation cohort, the model shows promise towards potentially facilitating optimal decision-making for the small, sub-cm, difficult nodules that prolifically populate LDCT screening programs.

P1.04.19 Evaluating the Impact of Electronic Reminders on Lung Cancer Screening

D.N. Kamtam, C.C. Chang, Y. Weng, I.A. Elliott, B.A. Guenthart, D.Z. Liou, L.M. Backhus, M.F. Berry, J.B. Shrager, A.J. Phadke, S.S. Han, N.S. Lui
Stanford University, Stanford/CA/USA

Introduction: Adherence to lung cancer screening (LCS) guidelines remains a significant challenge in clinical practice. Our healthcare system implemented a program of electronic reminders for LCS and we assessed its effectiveness in improving LCS rates over a one-year period.

Methods: The electronic reminders program implemented in our electronic medical record system alerts primary care physicians when patients eligible for LCS are overdue for their annual low-dose computed tomography scan. We identified patients included in the electronic reminders program at implementation in 2022 and categorized them as either “Screened within one year” or “Overdue for screening.” The primary outcome was whether patients were screened within one year following implementation. To examine the association of patient demographics and clinical characteristics with the primary outcome, a logistic regression model was utilized, and the findings were visualized using a forest plot.

Results: Among the 8,406 patients eligible for LCS in the electronic reminders program, the mean age was 66.5 years and 5,135 (62%) were male. The 779 (8.9%) patients Screened at rollout were younger (62.1 vs. 67.0 years, SMD -0.50) (Table). Overall, screening rates significantly increased from 8.9% to 15.7% (p<0.001) at one year following implementation (Figure). Among those Screened at rollout, 51% were screened within one year following implementation. Among those Overdue at rollout, 13% were screened at one year following implementation; those who were screened were more likely to have a family history of cancer (OR: 1.97; 95% CI:1.23-3.05, p=0.006), part-time/unemployed status (OR: 1.48; 95% CI:1.23-1.78, p<0.001), and Black race (OR: 1.43; 95% CI:1.08-1.88, p=0.002), while patients who were currently smoking were less likely to undergo screening at one year (OR: 0.82; 95% CI 0.70-0.95, p=0.008).

Conclusions: While electronic reminders can enhance LCS adherence, targeted interventions are necessary to address disparities in screening adherence, particularly among high-risk populations.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.20 Barriers to Lung Cancer Screening Among Overdue Patients; a Quality Improvement Initiative

S. Choudhary[1], J. Shi[1], J. Kim[1], C. Chang[1], N. Kapula[1], J. Wang[1], L. Shula[2], K. Chang[1], N. Lui[1]
[1]Stanford University, Palo Alto/CA/USA ,[2]Stanford Health Care, Palo Alto/CA/USA

Introduction: Lung cancer is the leading cause of cancer mortality in the US, but screening rates remain low. We explored barriers to lung cancer screening (LCS) in patients overdue for an annual low dose computed tomography (LDCT).

Methods: We identified patients eligible for LCS in primary care clinics within an academic healthcare system, distinguishing those Screened for lung cancer in the past year from those Overdue for screening. Logistic regression was used to investigate predictors of being Overdue for LCS. We conducted phone interviews with Overdue patients and utilized thematic analysis to identify barriers to LCS. IRB exemption was granted for this quality improvement study.

Results: We identified 290 patients eligible for LCS, including 105 Overdue patients (Table). Overdue patients were younger (64 vs. 67 years, p=0.031), more likely to be working (64% vs. 52%, p=0.049), and less likely to have seen their primary care physician within the past year (86% vs. 95%, p=0.01). In multivariable analysis, patients who had not seen their PCP within the past year were more likely to be Overdue (OR 3.41; 95% CI, 1.41-8.57; p=0.007). Of the 105 Overdue patients, 47 patients participated in phone interviews (Figure). Of those, 17 (36%) were not aware of lung cancer screening. When asked about barriers, 19 (40%) cited “other pressing medical/personal issues,” 8 (17%) “didn’t understand LCS or its guidelines,” 4 (8.5%) “felt unheard or PCPs were too busy,” and 7 (15%) had “anxiety about LCS and its findings.” Following the interview, 34 (72%) were interested in LCS.

Conclusions: Most patients overdue for screening were not aware of LCS and less likely to have seen their PCP within the past year. 72% of patients who participated in the phone interviews expressed interest in screening. Targeted education and proactive primary care engagement are key to improving LCS rates.

P1.04.21 Molecular Profiles of Clinical and Radiological Features in Pre-Invasive Lung Adenocarcinoma

Y-D. Lin, H-J. Li, H-Z. Hong, Y-F. Qi, Z-B. Qiu, R. Fu, Y-L. Wu, W-Z. Zhong
Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN

Introduction: Pre-invasive lesions as the initial phrase of lung adenocarcinoma, involve adenocarcinoma in situ (AIS) and minimally invasive adenocarcinoma (MIA), which are critical and curable points for surgery. Diagnosis of early-stage lesions is primarily through imaging, while the biological phenotypes are well reflected in the imaging. However, there is limited research on the relationship between the clinical, radiological features, and molecular profiles of pre-invasive lesions.

Methods: 371 pre-invasive lesions samples with next-generation sequencing (NGS) were for incorporated analysis, investigated the relationship between the mutational landscapes, clinical information and radiological features. Radiological features included marginal spiculation, bubble lucency, cystic airspace, pleural retraction, pleural attachment, lobulation, vessel convergence, vessel crossing and air bronchogram.

Results: The proportion of RET rearrangements (3.23%) was higher than ALK (2.43%) in pre-invasive lesions. Patients with EGFR tended to be older (median 52 vs 48 years, P=0.004), while those with ERBB2 (median 44 vs 51 years, P<0.001) and gene rearrangements (median 40 vs 50 years, P=0.002) were younger. MIA demonstrated a significantly higher of pleural retraction (31.04% vs 13.89%, P=0.032). ERBB2 was significantly enriched in marginal spiculation (46.75% vs 29.25%, P=0.004). Gene rearrangements showed strong association with bubble lucency (86.96% vs 65.52%, P=0.034). RET (33.33% vs 11.70%, P=0.049) and EGFR 19Del (17.74% vs 7.76%, P=0.044) were enriched in cystic airspace. EGFR exhibited positive correlation with pleural retraction (34.27% vs 24.87%, P=0.047), whereas KRAS mutations demonstrated inverse association (9.09% vs 30.66%, P=0.031). The frequency of ALK was higher in pleural attachment (66.67% vs 27.07%, P=0.017), while KRAS again displayed inverse association (9.09% vs 29.23%, P=0.041).

Conclusions: Our study demonstrated the molecular features of pre-invasive lesions in a relatively large data, helping to analyze the biological phenotypes in radiological perspective, and providing a reference for surgical intervention during this curable window.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.22 The Relationship Between Nodular Pleural Tail Sign and Metastasis or Recurrence of Peripheral Lung Cancer

A. Yu[1], Y. Shi[1], C. Hong[1], S. Tao[2], Q. Li[1], X. Li[1]
[1]The First Affiliated Hospital of Hainan Medical University, Haikou/CN ,[2]Quartic.ai, Toronto/ON/CA

Introduction: This article aimed at exploring the effectof nodular pleural tail sign formed by MIP reconstruction to predict lungcancer invasiveness.

Methods: 55 cases ofperipheral lung cancer with pleural tail sign were collected throughthin-section imaging. The cohort included 35 males and 20 females, with a meanage of 60 years (range: 32-75).Severalreconstruction thicknesses ranged from 0.625 mm to 1.5 mm were available, andthe intervals were equal to each corresponding thickness using a standardreconstruction algorithm, lung window, window width, 1000 HU; window level -700HU. Maximum intensity projection (MIP) slab thickness was five times theoriginal slice thickness resulting in 5-line opacities of interlobar fissure orpleural tail-sign on lung window of unsharpened image, which was known as5-line sign. Nodular tail sign (NTs) and non-nodulartail sign (N-NTs) are challenging to distinguish on conventional thin-sectionCT images, necessitating MIP reconstruction for enhanced visualization. The NTson MIP reconstruction demonstrates two patterns: 1. The lines widened and fusedto form nodule; 2. The density of lines were so weak that the interstitialspaces hardly be observed, most of that accompanying ground glass nodule orsolid nodule. N-NTs refers to the MIP reconstruction image showing a smoothcontour with five lines and clear spaces between the lines.A logistic regression was carried out to assess the effectof sex, age, and NTs vs. N-NTs sign on the likelihood of metastasis orrecurrence.

Results: Among 55 cases (54 with non-small cell lungcancer, 1 with small cell lung cancer), 44 cases showed NTs (Figure),of which30 cases were found metastasis on preoperative imaging and postoperativepathology, in remaining 14 cases, 7 cases were found recurrence and metastasisduring imaging follow-up 2 months to 4 years after surgery. The possibilityof NTs prediction on metastasis and recurrence was statistically significant($p<0.001$) and AUC-ROC is 0.861. Among 11 cases with N-NTs, only 1case was confirmed lymphatic metastasis by both image and pathology, theremaining 10 cases had no recurrence by follow-up 4 to 15 years after surgery. That imply that NTs highly indicate lung cancer metastasisor recurrence. NTs vs. N-NTs ($p<0.001$) was significant.Figure legends: MIP image shows a nodulartail sign (arrow), the patient was found adrenal metastasis 7months aftersurgery.

Conclusions: The nodular tail sign may represent lungcancer invasion into the pulmonary interstitium and is closely linked tometastasis or recurrence.

P1.04.23 Real-World Predictive Performance of Lung-RADS in the Evaluation of Part-Solid Nodules

S. You[1], M-S. Soh[1], Y.N. Kim[1], J.S. Sun[1], J.H. Park[1], B. Park[1]
[1]Ajou University School of Medicine, Suwon/KR

Introduction: Part-solid nodules (PSNs) are associated with a high malignancy rate and solid component of PSNs are important to predict malignancy. While the Lung-RADS aims to stratify risk and guide clinical management, its predictive value specifically in PSNs remains unclear. This study aims to evaluate the diagnostic accuracy and risk stratification performance of the Lung-RADS categories in PSNs.

Methods: We retrospectively reviewed CT reports of 4,382 participants who underwent lung cancer screening (LCS) between May 2017 and February 2025 at our institution. Among these, PSNs were identified and categorized according to Lung-RADS (2, 3, 4A, 4B, or 4X). The reference standard for malignancy was determined based on histopathologic confirmation or imaging follow-up. We evaluated malignancy rates across Lung-RADS categories and assessed the diagnostic performance of Lung-RADS in predicting malignancy in PSNs.

Results: Of the 79 PSNs identified, 54 nodules in 48 patients were included after excluding cases with indeterminate reference standards. The distribution of Lung-RADS categories was as follows: category 2, 18.5% (10/54); category 3, 46.3% (25/54); category 4A, 13.0% (7/54); and category 4B/4X, 22.2% (12/54). Overall, 24.1% (13/54) of PSNs were malignant. Malignancy rates by category were: 10.0% (1/10) for category 2, 16.0% (4/25) for category 3, 42.9% (3/7) for category 4A, and 41.7% (5/12) for category 4B/4X. When category 3 and above were considered screening positive, the sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were 92.3%, 22.0%, 27.3%, and 90.0%, respectively. When the threshold was set at category 4, the corresponding values were 61.5% for sensitivity, 73.2% for specificity, 42.1% for PPV, and 85.7% for NPV.

Conclusions: In part-solid nodules detected on screening CT, malignancy rates were higher than generally anticipated for lower Lung-RADS categories. The system showed high sensitivity but low specificity with a category 3 threshold, and the distinction between categories 4A and 4B/4X provided limited additional stratification. These findings suggest that Lung-RADS may have limited predictive accuracy for part-solid nodules and underscore the need to improve risk stratification approaches for this subgroup in clinical practice.

P1.04.24 TabPFN Empowered the Ternary Classification of Histological Subtypes in Stage IA LUADs Based on AI Analyzed Histogram Features

G. Pei, Y. Huang
Beijing Haidian Section of Peking University Third Hospital: Beijing Haidian Hospital, Beijing/CN

Introduction: Preoperative differentiation of preinvasive, minimally invasive adenocarcinoma, and invasive adenocarcinoma subtypes in stage IA lung adenocarcinoma (LUAD) is critical for surgical decision-making. However, overlapping imaging features and interobserver variability hinder accurate classification. Existing AI models often focus on binary classification or lack multicenter validation. To develop and validate a transformer-based tabular foundation model (TabPFN) for ternary classification of LUAD subtypes using AI-derived histogram features and compare its performance with traditional machine learning (ML) algorithms and intraoperative frozen section analysis.

Methods: This multicenter retrospective study utilized preoperative CT scans from three institutions between September 2014 and October 2023. Data were divided into training, internal validation, and external test sets. Histogram features (n=26) were extracted using a commercial AI system (InferRead CT Lung). TabPFN and five ML algorithms were trained and validated across datasets. Performance was evaluated using accuracy, macro-AUC, sensitivity, specificity, and Cohen's Kappa. Statistical comparisons included DeLong tests for AUC and chi-square tests for categorical variables.

Results: The cohort comprised 584 patients with stage IA LUAD (mean age 57.9±11.0 years; 386 female), divided into training/validation sets (n = 412, center 1) and external test sets (n = 114, centers 2; n =58, center 3). TabPFN achieved macro-AUC of 0.784-0.906 and accuracy of 70.7%-79.4% across external test sets, outperforming all ML algorithms (e.g., XGBoost: 65.2%, AUC 0.721). On external test set 2, TabPFN's accuracy (70.7%) significantly exceeded frozen section analysis (43.1%, p=0.003). Subgroup analysis revealed superior performance for male patients (75.3%, AUC 0.89) and mixed ground-glass nodules (AUC 0.85-0.91).

Conclusions: TabPFN demonstrated robust ternary classification of LUAD subtypes across institutions, with superior performance compared to traditional ML and frozen section analysis. Its computational efficiency (<1 second per case) and sex/nodule-type specificity support its clinical utility for guiding personalized surgical strategies.

P1.04.25 Incidental Findings From the Annual Follow-Up in the 4-In-The-Lung-Run Lung Cancer Screening Trial

D. Han[1], A. Walstra[1], K. Togka[1], J. Rohof[1], M. Heuvelmans[1,2,3], J-W. Gratama[4], M. Silva[5], C. van der Aalst[6], H. de Koning[6], M. Oudkerk[1,7]
[1]Institute for Diagnostic Accuracy, Groningen/NL ,[2]Amsterdam Medical Center, Amsterdam/NL ,[3]University Medical Center Groningen, Groningen/NL ,[4]Gelre ziekenhuizen, Apeldoorn/NL ,[5]University of Parma, Parma/IT ,[6]Erasmus Medical Center, Rotterdam/NL ,[7]University of Groningen, Groningen/NL

Introduction: Lung cancer screening (LCS) with low-dose CT has been shown to reduce lung cancer-related mortality in high-risk individuals. However, LCS often detects incidental findings (IFs) that are not the primary focus of screening. These findings pose challenges for healthcare by increasing costs due to potentially unnecessary diagnostic procedures and causing anxiety among participants. This study examines IFs identified at baseline and during annual follow-ups in the European 4-In-The-Lung-Run (4ITLR) screening trial, with a particular focus on the clinical relevance of IF stability and progression for further work-up.

Methods: Chest LDCT scans from the first annual screening participants (n=2601), acquired between 12 February 2024 and 21 January 2025 from the Dutch 4ITLR centers were included in this study. IFs reported by radiologists were categorized by anatomical location: intrathoracic-intrapulmonary, intrathoracic-extrapulmonary, extrathoracic, and vascular. If IFs were evaluated as potentially clinically significant they were reported to the participant's general practitioner (GP).

Results: Among the 2,601 annual screening participants, 65 (2.5%) had IFs reported by radiologists, with a total of 70 IFs identified, as some participants had multiple findings. IFs were classified into four categories based on location: 23 (0.9%) intrathoracic-intrapulmonary, 14 (0.5%) intrathoracic-extrapulmonary, 18 (0.7%) extrathoracic, and 15 (0.6%) vascular. A total of 25 IFs (1.0%) were reported to GPs, including 9 (0.3%) that were either new or showed progression compared to previous examinations. No acute IFs were reported. Coronary calcifications and pulmonary emphysema were considered comorbidities, while Agatston calcium scores >300 were routinely reported to GPs.

Conclusions: In the annual screening round of the 4ITLR trial, only a limited number of IFs were reported, without any acute consequences over a one year period. Ongoing follow-up studies will help to determine if systematic reporting of IFs in LCS follow-ups will be of clinical benefit to screening participants.

Introduction: Brain metastases are common in patients with non-small cell lung cancer (NSCLC), yet the role of brain MRI surveillance in patients without initial brain metastases remains uncertain. This study aims to evaluate the cumulative incidence of brain metastases and the impact of brain MRI surveillance on survival outcomes in NSCLC patients without brain metastases at initial diagnosis.

Methods: We conducted a retrospective, single-institution cohort study of NSCLC patients diagnosed between September 2014 and December 2019. Patients who underwent staging brain MRI without evidence of brain metastases were categorized into surveillance and non-surveillance groups based on follow-up MRI status. Propensity score matching was used to balance clinical stage, histology, and actionable genetic alterations (AGAs). The primary outcome was the cumulative incidence of brain metastases, while overall survival (OS) was the secondary endpoint.

Results: A total of 6,448 patients met the inclusion criteria, with 2,236 (34.7%) undergoing brain MRI surveillance. The cumulative incidence of brain metastases was higher in patients with advanced-stage disease (0.4% vs. 4.8% vs. 6.9% at 1 year, 1.4% vs. 12.0% vs. 20.1% at 2 years for stages I-II vs. III vs. IV), particularly in patients with adenocarcinoma and specific AGAs (EGFR, ALK, ROS1 alterations). After propensity score matching, brain MRI surveillance was associated with significantly improved OS in stage IIIB/C (HR = 0.604; 95% CI = 0.389-0.936; P = 0.024) and stage IV (HR = 0.470; 95% CI = 0.390-0.566; P < 0.001). Subgroup analysis revealed that the survival benefit was linked to increased utilization of gamma knife radiosurgery and longer durations of tyrosine kinase inhibitor therapy.

Conclusions: Brain MRI surveillance in NSCLC patients without initial brain metastases was associated with improved survival outcomes, particularly in advanced-stage disease. These findings suggest that a risk-adapted approach to brain MRI surveillance may be beneficial, warranting further prospective studies to refine guidelines for brain metastasis monitoring in NSCLC.

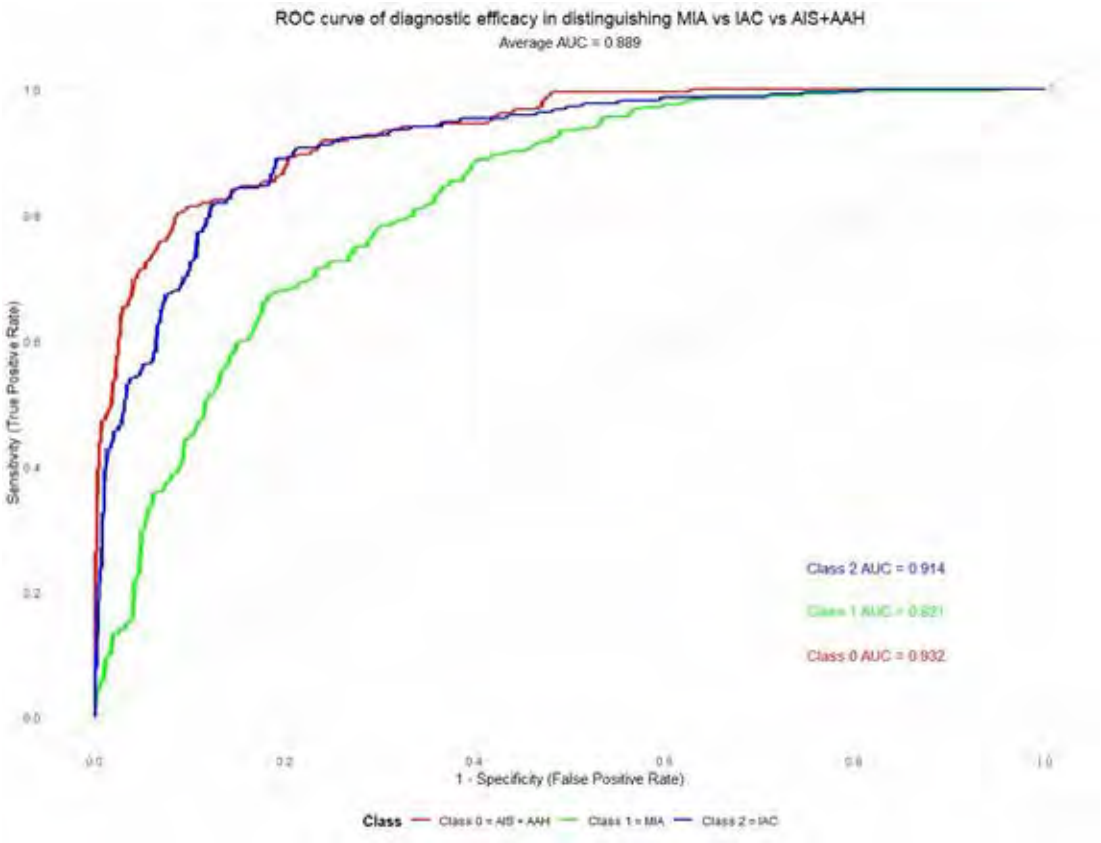
P1.04.27 Radiologic Features Identification of Pathologic Tumor Invasion in Pure Ground-Glass Nodules

Y. Zhu, Q. Wan, Q. Zou
The First Affiliated Hospital of Guangzhou Medical University, Guangzhou/CN

Introduction: Preoperative evaluation of the invasiveness of pure ground-glass nodules (pGGNs) at CT influences clinical decision-making but may be challenging. we aim to explore CT features of pGGNs of all histopathologic subtypes (atypical adenomatous hyperplasia or adenocarcinoma in situ, minimally invasive adenocarcinoma and invasive adenocarcinomas) and determine the radiologic model predicting pathologic invasiveness of pGGNs in a ternary classification.

Methods: A retrospective review was performed of 1683 patients between January 2012 and Jun 2024 who had suspicious pGGNs between 4.0 mm and 30.0 mm on preoperative CT. For each pGGNs, the size, location, margin, shape, nodule CT attenuation, uniformity of density, lobulation sign, reticulation sign, vascular cluster sign, bubble-like lucency sign, air bronchogram sign and pleural indentation sign were evaluated by two radiologists independently who were blinded with clinical information and pathology results. Ternary univariable and multivariable logistic regression and diagnostic accuracy analysis were used.

Results: 1683 patients (1145 [68.0%] female, 538 [32.0%] male) with median age of 53 years (IQR: 45-61 years). Among the 1683 patients, 2125 pGGNs were included. Ternary multivariable logistic analysis demonstrated that the independent radiologic factors for predicting pathologic MIA were age (OR=0.98, 95% CI: 0.97-0.99), nodule size (OR=1.22, 95% CI: 1.14-1.32), number of vessels (OR=3.31, 95% CI: 2.75-3.92), CT attenuation (OR=1.01, 95% CI: 1.00-1.01), uniformity of density (OR=1.77, 95% CI: 1.25-2.54), presence of pleural retraction (OR=2.10, 95% CI: 1.30-3.34), bubble lucency (OR=1.74, 95% CI: 1.02-2.95) and air bronchogram (OR=2.14, 95% CI: 1.16-3.99). Ternary multivariable logistic analysis demonstrated that the independent radiologic factors for predicting pathologic IAC were nodule size (OR=1.69, 95% CI: 1.56-1.84), distance to pleural (OR=1.04, 95% CI: 1.01-1.07), number of vessels (OR=2.77, 95% CI: 1.98-3.73), CT attenuation (OR=1.01, 95% CI: 1.01-1.01), uniformity of density (OR=5.67, 95% CI: 2.99-10.74), presence of lobulation (OR=2.08, 95% CI: 1.25-3.61), pleural retraction (OR=2.93, 95% CI: 1.66-5.00), bubble lucency (OR=2.40, 95% CI: 1.28-4.36) and air bronchogram (OR=2.92, 95% CI: 1.53-5.71). Overall, the diagnostic efficacy using the radiologic model to distinguish IAC vs MIA vs AAH/AIS was 0.89. There were 57 patients had enlarged mediastinal lymph nodes on CT. None of them had N1, N2 and N3 lymph node metastasis.



Conclusions: The independent radiologic factors for predicting pathologic invasiveness adenocarcinoma of pGGNs were nodule size, number of vessels, CT attenuation, presence of pleural retraction and bubble lucency and air bronchogram. Overall, the diagnostic efficacy using the radiologic model to distinguish IAC vs MIA vs AAH and AIS was 0.89.

P1.04.28 Correlation Between Dosimetric Parameters and Radiation-Induced Pulmonary Toxicity in Lung Cancer Radiotherapy

L.B. Assunção[1], R.B. Aguiar[1], G.L. Cunha[1], T.R. Dias[1], J.S. Pavão[1], M.T. Bento[1], C.E. Almeida[2], E. Fuks[2], P. Canary[2], G. Freire[2], R. Ferrari[2], L. Franco[2], J. Melo[3], D. Przybysz[2]
[1]Petropolis Medical School - FMP, Petrópolis/BR ,[2]RadioSerra, Petrópolis/BR ,[3]Oncology Therapy Center - CTO, Petrópolis/BR

Introduction: Radiation pneumonitis (RP) and pulmonary fibrosis remain critical concerns in lung cancer radiotherapy, significantly impacting patient outcomes and quality of life. International guidelines, including those by Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) and ASTRO, identify V20% (lung volume receiving ≥20 Gy) and Mean Lung Dose (MLD) as predictors of radiation-induced lung toxicity. This study investigates correlations between these dosimetric parameters and pulmonary toxicity among lung cancer patients treated in a Brazilian cancer center, hypothesizing that elevated V20% and MLD correlate with increased pulmonary toxicities.

Methods: This analysis was conducted on lung cancer patients who underwent definitive or palliative radiotherapy between 2020 and 2025 at a single institution. Dosimetric parameters, including MLD, V20%, Dmax, V35%, V50%, and V60%, were extracted from treatment plans. Pulmonary toxicities were graded using CTCAE v5.0, with a focus on Grade ≥2 RP and pulmonary fibrosis. A multivariate analysis was performed to assess the association between dosimetric variables and toxicity incidence, with $p<0.05$ considered statistically significant.

Results: Among the analyzed patients, 18% developed Grade ≥2 RP, with a significantly higher incidence (28% vs. 12%, p=0.002) in individuals with V20% >30%. The mean V20% was updated to 1.80% (SD ±6.87%) and patients exceeding this threshold demonstrated an increased risk of pulmonary complications. Pulmonary fibrosis was more prevalent in cases where MLD exceeded 4520.92 cGy (p=0.006). Higher values of V35% and V50% also showed a trend toward increased toxicity, reinforcing the importance of limiting high-dose exposure to normal lung tissue. These findings align with international dosimetric constraints, which recommend maintaining V20 ≤35% and MLD ≤20 Gy to minimize RP risk, confirming that V20% and MLD are strong predictive markers for radiation-induced pulmonary toxicity in lung cancer patients receiving radiotherapy. This study reinforce the universal applicability of established dosimetric thresholds and highlight the importance of individualized treatment planning to mitigate toxicity risks while ensuring effective tumor control.

Conclusions: Modern radiation techniques, such as intensity-modulated radiotherapy (IMRT) and volumetric modulated arc therapy (VMAT), may significantly reduce pulmonary complications. These results emphasize the necessity of refining dosimetric constraints and personalized protocols to enhance radiotherapy safety. Future prospective studies are warranted to further validate these findings and optimize treatment strategies for lung cancer patients.

Introduction: Lung cancer screening programs historically target individuals with a history of tobacco use. However, growing evidence indicates that never-smokers with risk factors, such as a family history of lung cancer or specific demographic profiles, may also benefit from screening. FANSA represent a distinct subgroup often defined by actionable oncogenic drivers, better treatment options at advanced stage, and generally lower comorbidity burden. This study aimed to compare stage-specific overall survival (OS) and cancer-specific survival (CSS) between FANSA patients and other NSCLC patients, and to evaluate the independent impact of FANSA variables; sex, ethnicity, smoking status, and histology on survival outcomes.

Methods: A retrospective pooled analysis of NSCLC patients was performed from 25 International Lung Cancer Consortium (ILCCO) sites across North and South America, Asia and Europe (1990-2020). Multivariable Cox and Fine-and-Gray regression were used to assess survival by stage and identify key drivers of OS and CSS (primary outcomes), with subgroup analyses focusing on stage 1 patients and comorbidity profiles.

Results: Of 36,966 patients, 1,837 were identified as FANSA. FANSA patients had superior OS across all stages compared to ever-smokers and other never-smokers (stage-I hazard ratio (HR) 0.16, 95%CI: 0.12-0.21; stage-II/IIIA HR 0.48, 95%CI: 0.40-0.57; stage-IIIB/IV HR 0.53, 95%CI: 0.48-0.60; all p<0.001). The most pronounced survival benefit was observed in Stage I FANSA patients (5-year OS: 93% for FANSA, 79% other never-smokers, 61% ever-smokers, p<0.001). Interaction analyses revealed that the relationship between OS and sex, ethnicity, smoking status, and histology varied significantly by stage (all p<0.001). In stage I, multivariable Cox analysis revealed that female sex (adjusted (a) HR, 0.74; 95%CI: 0.69-0.78, p<0.001), Asian ethnicity (aHR 0.73; 95%CI: 0.56-0.96, p=0.03), never-smoking (aHR 0.53; 95%CI: 0.47-0.59, p<0.001), and adenocarcinoma histology (aHR 0.72; 95%CI: 0.67-0.77, p<0.001) were each independently associated with improved OS. FANSA patients were younger (median age 60 vs 64 in other never smokers, 66 in ever smokers, p<0.001) and had fewer comorbidities, including respiratory (6% FANSA vs 28% in other patients, p<0.001) and cardiovascular comorbidities (25% FANSA vs 37% other patients p<0.001). In patients with available CSS data, FANSA patients demonstrated improved CSS within five years of diagnosis (p<0.001) with the strongest association in stage I (HR 0.21; 95%CI: 0.15-0.29); though this was also evident in stage II/IIIA (HR 0.60; 95%CI: 0.49-0.73) and stage IIIB/IV (HR 0.77; 95%CI: 0.69-0.87). In stage 1, more favourable CSS was associated with female sex (aHR 0.79; 95%CI 0.67,0.95, p=0.01), never-smoker status (aHR 0.63, 95%CI 0.49,0.82, p=0.002), and adenocarcinoma histology (aHR 0.77; 95%CI: 0.64-0.93, p<0.001), though ethnicity was not significantly associated with CSS (p=0.3).

Conclusions: FANSA patients demonstrate significantly better survival outcomes, particularly with stage I disease. This favorable prognosis may be attributed to younger age at diagnosis and lower comorbidities but it may also reflect unique tumor biology. Given the improved outcomes with early diagnosis, these findings further support the contention that early detection of FANSA in its earliest stages can lead to substantial survival benefits. These findings support the inclusion of select female Asian never-smokers in lung cancer screening programs.

P1.04.30 Screening of Paraptosis-Related Prognostic Genes in Lung Adenocarcinoma By Bioinformatics Analysis and Experimental Validation

T. Zhang[1], S. Tang[2], J. Zhang[1]
[1]Shenzhen Hospital, Southern Medical University, Shenzhen/CN ,[2]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Guangzhou/CN

Introduction: Paraptosis is a key cell death mode for cancer cells to produce anti-tumor effects, but its role in lung adenocarcinoma (LUAD) is not fully understood. This paper attempts to comprehensively study the prognostic value and potential mechanisms of paraptosis-related genes (PRGs) in LUAD.

Methods: Differentially expressed genes (DEGs) were identified from LUAD vs. control samples in the training set, intersected with PRGs to generate candidate genes (CGs). Prognostic genes were then screened from CGs using regression analyses to create a LUAD risk model, validated in the validation set. Clinical characteristics were analyzed to derive independent prognostic factors for a nomogram model. High-/low-risk cohorts from the training set underwent function and immune infiltration analyses. Drugs related to prognostic genes were predicted and docked, and Polymerase chain reaction (PCR) was conducted to validate the prognostic genes.

Results: Based on 27 CGs, 4 prognostic genes (CDKN3, PEBP1, TNFRSF19, PHB) were identified through regression analysis. The prognostic risk model effectively predicted LUAD prognosis and was generalizable. Risk scores showed significant differences in age, T-stage, and N-stage ($P < 0.05$). Risk score, T-stage, and N-stage were independent prognostic factors used to develop a nomogram model, a strong LUAD predictor. High-/low-risk cohorts were enriched in functions like spindle elongation and correlated with differential immune cells. Vorinosta and raloxifene were key drugs binding well to PEBP1. CDKN3 was highly expressed in LUAD, while PEBP1 and TNFRSF19 were lower.

Conclusions: In this study, we focused on PRGs for CDKN3, PEBP1, TNFRSF19, and PHB. CDKN3 and PHB were identified as risk factors for LUAD prognosis, while PEBP1 and TNFRSF19 were not. We explored the tumor microenvironment, revealing the distribution and correlation of differential immune cells influenced by PRGs and riskScore. Besides,we uesd PCR to validate the prognostic genes. However, the specific relationships between some PRGs and immune cells remain unclear and were not fully investigated in our study. Additionally, we developed an independent prognostic model for LUAD and enhanced the functions and pathways of high- and low-risk cohorts. Our drug prediction study provided insights into potential therapeutic directions for LUAD, but further research is needed.

P1.04.31 Implementation of a Lung Cancer Risk Prediction Algorithm: Early Findings From the Lungflag™ Pilot at Geisinger Health System

M.A. Facktor[1], R. Maff[1], C. Keister[1], E. Mitchell[1], Y. Jin[2], T.G.N. Ton[3], N. Olghi[4], M. Obradovic[4]
[1]Geisinger, Danville/PA/USA ,[2]Roche Molecular Systems Inc, Santa Clara/CA/USA ,[3]Genentech, South San Francisco/CA/USA ,[4]F. Hoffmann-La Roche Ltd, Basel/CH

Introduction: The Lung Cancer Screening (LCS) program has been implemented at Geisinger since October 2020. Integration of new technologies into clinical workflows holds a promise to improve LCS. LungFlag™ (Medial EarlySign, Hod Hasharon, Israel) is a machine-learning-developed model allowing further risk stratification in the LCS eligible population, predicting individuals who may be at risk for certain respiratory illnesses including lung cancer, enabling targeted recommendation for low-dose computed tomography (LDCT) screening if one was not performed. Geisinger piloted this model from August 2023 to August 2024. Here, we report the early results of the pilot program in a real-world healthcare setting.

Methods: This pilot study integrated LungFlag into routine clinical practice via the hospital's electronic medical record system. LungFlag performs monthly risk evaluations for individuals aged 50-80 eligible for annual lung cancer screening per US Preventive Services Task Force (USPSTF) recommendations. Patients with cancer history and those screened or scheduled for screening in the past year were excluded. Each month, LungFlag flagged 30 individuals with the highest risk scores (LungFlag+). A nurse navigator contacted LungFlag+ individuals with up to three phone calls, notifying them of their status and encouraging them to seek clinical assessments. Individuals who were not flagged (LungFlag-) continue receiving standard care, which includes reminders for LCS during routine visits without additional targeted outreach. This early evaluation focused on screening eligible LungFlag+ and LungFlag- individuals within the initial period from August 2023 to February 2024. Pilot outcomes, including screening compliance and findings from LDCT, are monitored during the follow-up period through August 2024.

Results: During the first six months of the pilot program, 180 individuals from the LCS USPSTF recommended population were flagged as LungFlag+, while 12,893 individuals were not flagged (LungFlag- group). Among the LungFlag+ group, 32 individuals (18%) were excluded after the LCS nurse navigator's chart review due to ineligibility (e.g., non-Geisinger primary care providers (PCPs) and incompatible insurance policies). No chart review was done for LungFlag- group. The 6-month compliance rate for the remaining 148 LungFlag+ individuals was 46% (n=68) for any chest CT and 29% (n=43) for LDCT. Assuming the same exclusion rate for the LungFlag- group, the compliance rates were 15% for any chest CT and 7% for LDCT. Additionally, the time between flagging to chest CT/LDCT was significantly shorter for LungFlag+ individuals, with a median of 26 days compared to 64 days for the LungFlag- group. While clinical impact results are still preliminary, among those who received a LungRADS categorization, the LungFlag+ group was 2.5 times more likely to have "suspicious" findings (LungRADS category 4; 14.3%) compared to the LungFlag- group (5.7%).

Conclusions: Early evaluation of the LungFlag pilot at Geisinger showed that combining AI-developed personalized risk assessment with nurse navigator support led to higher screening compliance rates and reduced waiting times. Based on clinical findings of initial individuals, LungFlag also shows the potential to enhance the efficiency of lung cancer screening programs by identifying more suspicious cases, monitor findings sooner and begin early intervention.

P1.04.32 Moving Forward in Early Detection: The ACS/NLCRT Best Practice Guide for Building Lung Cancer Early Detection Programs

C.C. Thomson[1,2], M. Gieske[3], V. Beckler[4], D. Dyer[5], G. Silvestri[6], L. Rosenthal[7], E. Kazerooni[8], R. Smith[7]
[1]Mount Auburn Hospital/Beth Israel Lahey Health, Cambridge/MA/USA ,[2]Harvard Medical School, Boston/MA/USA ,[3]St. Elizabeth Medical Center, Edgewood/KY/USA ,[4]AstraZeneca, Wilmington/DE/USA ,[5]National Jewish Health, Denver/CO/USA ,[6]Medical University of South Carolina, Charleston/SC/USA ,[7]American Cancer Society, Atlanta/GA/USA ,[8]University of Michigan, Ann Arbor/MI/USA

Introduction: Early detection of lung cancer includes both lung cancer screening (LCS) and management of incidental pulmonary nodules (IPNs), and should be a priority to achieve curative-intent treatment, better outcomes, and reduced costs. Yet, most health systems lack a coordinated approach to patient management and tracking for this purpose. LCS and IPN patient populations have different cancer risk, race/ethnicity, and insurance profiles that are important to address in program design. The ACS NLCRT developed the Best Practice Guide for Building Lung Cancer Early Detection Programs to help facilities create, expand, or improve their LCS and IPN programs.

Methods: Members of the ACS NLCRT Steering Committee and leadership of the Early Detection Task Group convened to create the scope and initial outline. Twenty individuals (clinicians, researchers, public health professionals) from 15 organizations (professional societies, advocacy organizations, health systems, industry) then developed the guide, beginning with a series of meetings with iterative feedback to refine the scope and content. Multiple subject matter experts with key informants from the Early Detection and the Provider Engagement Task Groups developed and refined content. This was then reviewed by an advisory committee, including individuals from key partner organizations, AstraZeneca Lung Ambition Alliance and Academy of Oncology Nurse & Patient Navigators, for optimization. Additional cycles of content development, review, and revision were completed prior to product launch in winter 2024.

Results: This guide has a broad audience (navigators, coordinators, providers, program leaders) and can be an essential resource in the work to advance early detection of lung cancer. It outlines 3 phases: 1) Needs Assessment and Making the Case, 2) Program Planning, and 3) Implementation and Sustainability. The guide contains numerous and valuable resources to support the development and optimization of early detection programs, including case studies, forms and data templates, risk calculators, and health equity tools. Links are embedded throughout the guide and compiled in a comprehensive resource section, highlighting many from ACS NLCRT member organizations. The materials are open access and free at the ACS NLCRT website @ https://nlcrt.org/best-practice-guide-early-detection/

Conclusions: The ACS NLCRT Best Practice Guide for Building Lung Cancer Early Detection Programs is a comprehensive, approachable, and flexible guide to building and optimizing LCS and IPN stand-alone or combined programs. This guide focuses on the basic steps to successfully plan and launch new programs and grow and enhance existing programs; it will be updated as major advances, new guidelines, or implementation strategies emerge.

P1.04.33 Sybil Pilot for Incidental Pulmonary Nodules

R.L. Myers[1], M. Brown[1], S. Borden[1], C. Bartolomeu[1], L. Shong[2], K. Bimbrahw[1], W. Chu[1], R. Hung[3], R. Meza[1], S. Lam[1]
[1]BC Cancer Research Institute, Vancouver/BC/CA ,[2]The University of Hong Kong, Hong Kong/CN ,[3]Lunenfeld-Tanenbaum Research Institute, Sinai Health, Toronto/ON/C

Introduction: A practical approach to expand early detection of lung cancer is to utilize CT scans already done commonly for non-screening purposes such as cardiac scans. Over 1.6 million patients with incidental pulmonary nodules (IPNs) are identified in the USA annually with an average lung cancer risk of 4-6%, higher than that of the LDCT screening eligible population. IPNs are identified on various scan types completed for other purposes that capture lung windows but usually require repeat low-dose CT scans to assess the nodule. Recently, artificial intelligence (AI) tools to assess medical images, such as Sybil, a deep-learning algorithm to predict 6-year lung cancer risk from a single LDCT scan, have captured attention. Sybil was developed and validated on low-dose lung screening scans. In this pilot, we compared Sybil's scores on a variety of diagnostic 'lung-in-view' and cardiac CT scans with IPNs to dedicated low-dose chest CT on the same individuals.

Methods: A cohort of prospectively and sequentially enrolled patients were included from the IDEAL trial, Vancouver site. All patients completed a dedicated follow-up LDCT chest (T1) which acted as a gold-standard reference for Sybil deep-learning analysis for comparison against their matched baseline (T0) CT scans.

Results: Eighty-five patients with IPNs detected on various CT scan types were identified: 39 (45.9%) cardiac (cardiac with contrast, coronary calcium score, left atrium), 22 (25.9%) high resolution chest without contrast and 20 (23.5%) chest with contrast, 4 (4.7%) neck/spine/shoulder were excluded. Mean time between T0 and T1 scans was 160±91.3 days. There were no statistically significant differences between T0 (4.8%) and T1 (4.4%) risk scores at each time-point over 6-years ($p>0.05$ for all). In a subgroup of patients with a cardiac T0 CT, no significant difference between Sybil scores at any time-point for T0 and T1 were observed ($p>0.79$). Pearson correlation demonstrated strong correlation (0.84) between T0 and T1 year 1 risk scores, decreased to 0.64 at year 6. Bland-Altman analysis showed excellent agreement in this subgroup between T0 and T1 with difference in mean risk of -0.31% for year 1 up to 0.46% at year 6 (Figure 1).

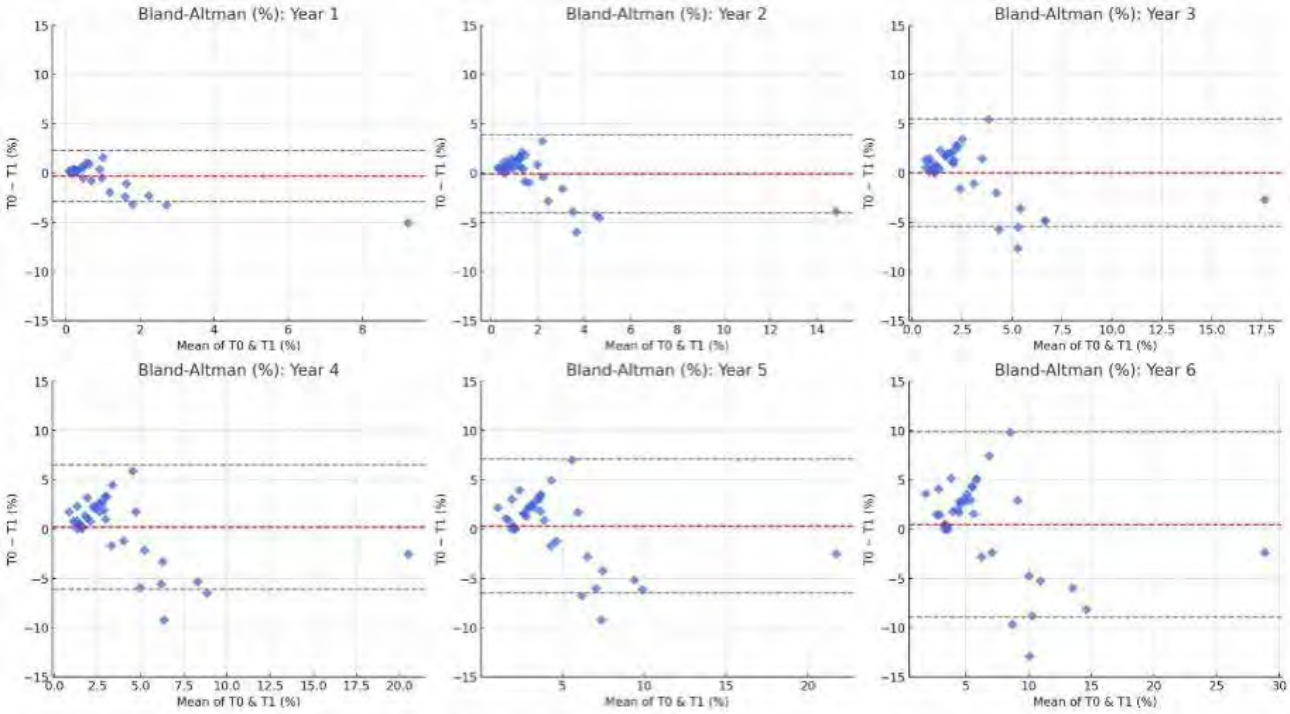

Figure 1: Bland-Altman analysis demonstrating strong agreement between baseline (T0) cardiac CT scans and low-dose CT chest (T1) risk scores for the same patients within an IPN cohort.

Conclusions: In this pilot study, Sybil scores were consistent between dedicated low-dose CT chest and various diagnostic CT scans, including cardiac scans. Further research is required to understand how AI and deep-learning algorithms can utilize pre-existing diagnostic imaging to opportunistically broaden the reach of lung cancer screening.

P1.04.34 AI Powered Incidental Pulmonary Nodule Program Demonstrates High Lung Cancer Detection Rate: Canadian IDEAL Study

R.L. Myers[1], M. Brown[1], C. Bartolomeu[1], S. Borden[1], K. Kiland[1], W. Parker[2], A. Mojibian[3], S. Lam[1], R. Hung[4]
[1]BC Cancer Research Institute, Vancouver/BC/CA ,[2]Vancouver General Hospital, Vancouver/BC/CA ,[3]University of British Columbia, Vancouver/BC/CA ,[4]Lunenfeld-Tanenbaum Research Institute, Sinai Health, Toronto/ON/CA

Introduction: Lung cancer screening has demonstrated a ≥20% mortality reduction in lung cancer through early detection in a high-risk ever smoking population. However, the majority of pulmonary nodules are found incidentally on imaging studies unrelated to screening. Recent studies demonstrate that the majority of patients with incidental pulmonary nodules (IPNs) are not receiving guideline follow-up despite a high incidence of lung cancer in this population. To engage patients with IPNs and broaden the reach of screening and early detection, a systematic approach to identify, track, and manage IPNs for integration into a lung cancer care or screening pathway is required. The purpose of our study is to evaluate a Natural Language Processing (NLP) model that will automatically identify patients with IPNs and create a 'fail-safe' pathway to improve triage and management of IPNs and ultimately increase early detection of lung cancer.

Methods: The Vancouver site of the multi-center IPN Canadian trial - the 'Identifying Early Lung Cancer in a Diverse Population' (IDEAL) study, evaluated a customized, ethics approved, RoBERTa-based transformer model, (SapienNLP) screening tool to screen all "lung-in-view" unstructured CT radiology reports within a large health authority, consisting of 4 major hospitals to identify patients between 50-80 years who have one or more lung nodules ≥ 6 mm. The model scanned the radiology information system every 24-hours for new reports. The list was then screened by a Respirologist to confirm patient's nodules were truly incidental. Patients with a confirmed IPN were invited to be enrolled in the IDEAL study to track and manage their nodules. The participants also underwent lung cancer risk assessment using the PLCOm2012 to determine the proportion of patients who may meet current British Columbia lung cancer screening criteria of >1.51% 6 -year lung cancer risk.

Results: Between November 1, 2023, and March 1, 2025, 66,173 'lung-in-view' radiology reports were analyzed, 17,783 (26 %) of scans identified pulmonary nodules, and 4916 (28%) of these had nodules ≥ 6mm in individuals aged 50-80 years. A total of 596 (12%) nodules were confirmed as true IPNs by a Respirologist. Notably, 215 (36%) of IPNs were identified on cardiac scans. Of the 204 participants enrolled (50% female, 60% non-tobacco users) only 18 (8.8%) were eligible for screening based on PLCOm2012 risk score >1.51%. Lung cancer incidence was 3.9% compared to 1.6% in the screening cohort, with 75% of IPN cancers diagnosed at stage I.

Conclusions: Integration of a natural language model enables efficient identification of patients with IPNs from a large number of lung-in-view CT imaging studies. A significant proportion of these patients were found to have lung cancer but were ineligible for screening. An IPN program provides a complementary method to current lung cancer screening programs, to detect and treat lung cancer early and improve outcomes.

P1.04.35 Impact of lung cancer screening eligibility criteria on participants' characteristics and healthcare resources

M.O. Cabrera[1,2], K. ten Haaf[3], J.M. Borràs[1,4], R. Font[4], J. Solà[4], M. Ballesteros[4], J.A. Espinàs[1,4]
[1]Bellvitge Biomedical Research Institute (IDIBELL), L'Hospitalet de Llobregat (Barcelona)/ES ,[2]Universitat de Barcelona, Barcelona/ES ,[3]Erasmus MC, University Medical Centre Rotterdam, Rotterdam/NL ,[4]Department of Health, Barcelona/ES

Introduction: Selectioncriteria for lung cancer screening (LCS) candidates are essential forimplementing resource-and cost-efficient programs. However, different selectioncriteria may have similar resource requirements but select dissimilarindividuals. This study explores the impact of different inclusioncriteria on eligibility, participants' characteristics and health services inSpain.

Methods: Across-sectional study was conducted using data from 21,007 individuals from the2012 Spanish National Health Survey (ENSE). We analyzed data from the 2012 Survey, the most recent withcomplete data on people who smoke and people with a smoking history. Theproportion of eligible individuals aged 50-80 years was assessed according tofour different LCS criteria. Two criteria were based on the 4 IN-THE-LUNG-RUNtrial; 4ITLR1: ages 60-79, who smoked at least 35 pack-years and currentlysmoke or quit smoking <10 years ago, and 4ITLR2: ages 60-79 who have aPLCOm2012 no race model risk of at least 2.6%. The third criteria was based onthe United Kingdom's Targeted Lung Health Check (TLHC): ages 55-74 with aPLCOm2012 risk of at least 1.51%. Finally, the 2021 United States PreventiveServices Task Force (USPSTF) criteria were evaluated: ages 50-80 who smoked atleast 20 pack-years and currently smoke or quit smoking <15 years ago. Theseestimates were extrapolated to the 2022 Spanish population using data from theNational Institute of Statistics (INE). Eligibility across sex, age groups andsmoking status was evaluated. For the estimation of LCS resource impact, annualand biennial intervals were chosen.

Results: In 2022, among the Spanish population aged 50-80 years(17,651,476individuals), the most restrictive lung cancer screening (LCS) criteria, 4ITLR1, identified 998,760 eligible individuals (5.6% of ages 50-80).The 4ITLR2 criteria included 1,188,790 eligible individuals (6.7% of ages50-80), rising to 1,875,926 (10.6% of ages 50-80) for the TLHC criteria. TheUSPSTF criteria were the broadest, identifying 3,806,525 eligible individuals(21.6% of ages 50-80). Annual screening (with 50% participation) ranged from499,380 participants with the most restrictive criteria (representing an 9.0%increase in national radiological capacity) to 1,903,262 (34.1% increase innational radiological capacity) with the broadest. For biennial screening,these numbers would be halved. All criteria primarily selected men(68.1-82.2% of eligibles). Most criteria favored selecting former smokers(49.4-56.9%). However, eligible women were more often current smokers than menacross all criteria (men: 38.5-46.8%, women: 50.0-64.2%). Former smokers smokedmore cigarettes per day than current smokers (30 vs 20) despite having shortersmoking durations, resulting in higher median pack-years across all criteria(range: 44-66). Overall, pack-year-basedeligibility decreased with age, while risk-based eligibility was stable acrossage groups.

Conclusions: In conclusion, different LCS inclusion criteriadirectly impact required healthcare capacity and yield populations with highly variedcharacteristics. Consequently,balance across these characteristics (age, sex, smoking behavior) should betaken into consideration when choosing the selection criteria.Risk-basedcriteria may provide more balanced eligibility across age-groups.

P1.04.36 LungFlagTM Risk Prediction Validation on Canadian Ever Smokers Pre-Classified as High Risk for Lung Cancer

S. Atkar-Khattra[1], Y. Yin[2], A. Lanyado[3], E. Israeli[3], M. Obradovic[4], A. Walker[1], S. Leong[1], A. DyBuncio[1], R. Myers[1], E.N. Choman[3], S. Lam[1]
[1]BC Cancer Research Institute, Vancouver/BC/CA ,[2]Hoffman-la Roche, Santa Clara/CA/USA ,[3]Medial EarlySign, Hod Hasharon/IL ,[4]Medical Affairs, Basel/CH

Introduction: The usage of personalized risk scores is increasingly adopted to evaluate specific clinical condition susceptibility. Early detection of Lung Cancer (LC) is clinically important as it translates to more favourable patient outcomes. Thus, development of population health management approaches using risk predictors (i.e. PLCOm2012 and EHR based LungFlag) for identification of individuals who may be in increased probability for having lung cancer is of paramount importance.

Methods: LungFlag (Gould, M.K.et al., 2021. Machine learning for early lung cancer identification using routine clinical and laboratory data. American journal of respiratory and critical care medicine, 204(4), pp.445-453) performance was assessed on a cohort biased towards high risk population, included two independent Canadian data sets (British Columbia) selected in the past for LC screening (1) Lung Screening Population (LSP) - (age: 55-80 years with ≥30 years smoking history who meet either the PLCOm2012 ≥ 1.51% or USPSTF 2013 criteria) and non-eligible population, and (2) the PanCan single-arm longitudinal trial (age: 50-75 years and ≥2% six years lung cancer risk). Sensitivity analysis was performed on combined populations. LungFlag was compared with PLCOm2012 for non-inferiority. LungFlag was not used to select individuals from the ever-smoking populations, disadvantage the algorithm to an already pre-selected population in the USPSTF/PLCOm2012 cohort.

Results: Out of a total population of 3,064 individuals, 2,958 (LSP: eligible - 2,171; non-eligible-703, and PanCan: 84) met the eligibility criteria including 49 LC (mainly due to 2 years prediction time horizon). The average age for cases was 69.0 with 42.9 years smoking duration compared to 64.9 and 36.5 for controls respectively. The proportion of participants with COPD was 35% compared to 14%, cases vs. controls, respectively. The overall AUC (2-years time horizon) on those who had ever smoked between age 50-80 years was comparable between LungFlag and PLCOm2012 (0.707 vs 0.693) (Figure 1), with similar trends on the USPSTF2013 criteria (0.687 vs 0.682) subpopulation.

Conclusions: Despite being conducted among the mostly pre-selected high-risk population, LungFlag consistently demonstrates non-inferior performance compared to the PLCOm2012 or the USPSTF2013 eligibility criteria. The model is applicable to Canadian EHR data. Using a 2-year risk horizon performed comparably well as 6 years horizons. Future studies should focus on prospective evaluation of LungFlag as an independent classifier to identify populations with an elevated risk of lung cancer for screening.

P1.04.37 Systematic Enrolment for Lung Cancer Screening Ensures Rapid Stage Shift of Diagnosed Lung Cancers at a Population Level

T. Laisaar[1], B. Sarana[1], A. Poola[1], M. Räppo[2], M. Taur[1], E. Kelner[2], P. Ilves[1], K-T. Laisaar[2]
[1]Tartu University Hospital, Tartu/EE ,[2]Tartu University, Tartu/EE

Introduction: Several studies have demonstrated that screening enables lung cancer (LC) detection at earlier stages. However, limited data exists about the effect of screening at population level. The aim of the study was to compare stage distribution and surgical treatment of LC in one region before and after implementation of systematic LC screening (LCS).

Methods: All LC cases, diagnosed in Tartu County in Estonia during 1.01.2021-30.06.2024 were included. In 1.04.2022, a regional LCS pilot study was initiated - individuals aged 55-74 years with elevated LC risk were enrolled by family physicians, who systematically assessed their patients to determine the target group. In the 2nd pilot study year, new individuals were recruited by family physicians, yet reinvitations were done by LCS coordinators. Screening low-dose computed tomographies (LDCT) were performed during 01.05.2022-31.05.2024. Study data was extracted from the pilot study database and hospital case reports.

Results: At the beginning of the pilot study 157758 individuals lived in Tartu County. There were 92 family physicians (74 participated in 1st and 87 in 2nd study year). The target age group in participating family physician practices was 26759 individuals at 1st and 31537 at 2nd year. Altogether during the two years of screening 8210 individuals were referred to LDCT and 7746 (94.3%) attended it - 64 LCs were diagnosed. Respectively, 34 (53%), 9 (14%), 10 (16%) and 11 (17%) in stage I, II, III and IV; 45 LCs (70%) were treated surgically. In Tartu County, in 2021, 75 LCs (17% in stage I and 53% in stage IV) were diagnosed. During the screening years a considerable LC stage shift at diagnosis in whole county was noticed (Figure 1). By the first half of 2024, out of the 58 LCs 36% were in stage I and 40% in stage IV. Also, the proportion of LCs diagnosed due to screening gradually increased to 38% by 2024. After LCS initiation, 181 LCs were detected among individuals, belonging to the family physician practices participating in the screening pilot, and 41 in those not participating. Respectively, LC was detected in stage I in 35% and 17%; in stage IV in 34% and 63%; and surgical treatment was feasible in 44% and 24% of cases.

Conclusions: Population based LCS ensured rapid increase in early-stage detection and surgical treatment of LC. Due to high LCS uptake the results were demonstrated not only in the screened population, but at the county level.

P1.04.38 The Coincidental Findings of Lung Nodules With AI-Assisted Chest X-Rays in the Tuberculosis Screening Project

P. Susilparat
Phra Nakhon Si Ayutthaya Hospital, Phra Nakhon Si Ayutthaya/TH

Introduction: Lung cancer screening using chest X-ray with artificial intelligence to analyze abnormalities (AI-assisted chest X-ray) is an alternative screening tool used in many countries. Although chest X-ray is not as effective as low-dose CT scan in lung cancer screening, there are many advantages and interesting points of using AI-assisted chest X-ray, such as the ability to find small lung nodules better than reading the image by the doctor's eyes alone, reducing misdiagnosis, less radiation exposure, lower costs, community screening, being able to integrate the method with existing tuberculosis screening event at the same time, and considering refer for Low-Dose CT scan in cases where chest X-ray with AI detect lung nodules that are likely to be malignant.

Methods: The tuberculosis screening event in Phra Nakhon Si Ayutthaya District was implemented from February to May 2024. When chest X-ray images were obtained from the mobile X-ray vehicle, a two-step analysis process was performed: The first step involved a family physician reading the chest X-ray image results using Inspectra CXR v4 (Perceptra®, Bangkok) software artificial intelligence. If any abnormalities are found or there is a doubt, it will lead to the second step, which is to refer the results to a radiologist for reporting the official results. In the case of a suspected malignant lung nodule, the radiologist will read the results and provide recommendations for a chest CT scan.

Results: A total of 2,597 participants with chronic diseases were screened for tuberculosis, comprising 816 males (31.4%) and 1,781 females (68.6%), with an average age of 62.87 years. After reviewing the results of the 2-step chest X-rays, the lung nodules were detected. (Indeterminate Pulmonary Nodule: IPN) of various sizes and types, totaling 70 (2.70%). The radiologist recommended further examination by chest CT scan for 35 (1.35%). After a 1-year follow-up, 18 (0.69%) underwent chest CT scans as recommended, and 4 participants (0.15%) were found to have lung cancer. Cancer Detection Rate was 1.54:1,000.

Conclusions: Lung cancer screening integrated with tuberculosis screening, utilizing AI-assisted chest X-rays, has the potential to be implemented as a community screening tool. However, the steps taken after the first doctor uses AI to read the results and identify abnormalities in the lung nodules may be adjusted according to the appropriateness of the resources, which differ in each area and level of the healthcare service. In preparing the lung cancer screening system, the screening campaign period, equipment (including mobile X-ray vehicles and artificial intelligence systems), referral systems, service units, and health personnel who will provide further care, both in cases of lung cancer diagnosis and lung nodule follow-up, must be prepared. A campaign should also be launched to raise public awareness of lung cancer and recognize the importance of receiving lung cancer screenings.

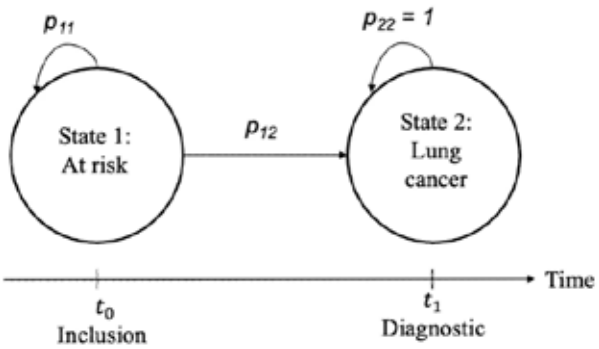
Introduction: We built a theoretical Markov Chain model to predict lung cancer diagnosis after a first round of lung cancer screening (LCS), to test it with real life data and to identify covariates useful for personalized risk stratification.

Methods: We developed a discrete-time Markov Chain model to simulate LCS outcomes after a first LCS round in the PREVALUNG and PREVALUNG ETOILE cohorts (NCT 03976804 and NCT 05649046). The model defined by the matrix Q, represents two states: "At risk" and "Lung Cancer" (Figure 1).

Figure 1: Markov Chain Model



$Q = \begin{bmatrix} p_{11} & p_{12} \\ 0 & 1 \end{bmatrix}$, with p_{ij}, probability of moving from state i to j

We used the msm package in R to build the model. Covariate effects (age, BMI (Body Mass Index), smoking history related covariates) were tested on probabilities pij, but only significant ones—smoking duration and exposure to additional carcinogens (silica, cadmium, arsenic, beryllium, diesel, nickel, coal smoke, soot, asbestos, cannabis)—were included.

Results: Table 1 presents the model-predicted and observed prevalence of each state at each time point.

Table 1: Observed vs Expected prevalences

		t_0	t_1
Observed	**State 1 (n (%))**	565 (100)	549 (97.2)
	State 2 (n (%))	0	16 (2.8)
Expected	**State 1 (n [95% CI] (% [95 % CI]))**	565 (100)	549 [538-555] (97.2 [95.2-98.2])
	State 2 (n [95% CI] (% [95 % CI]))	0	16 [10-27] (2.8 [1.8-4.8])

Smoking duration and additional carcinogen exposure significantly increased the risk of moving from state "At risk" to "Lung Cancer" (impact on p12) (HRsmoking_duration (Hazard Ratio): 2.39 [95% CI: 1.35-4.22], HRcarcinogens: 3.05 [95% CI: 1.14-8.21]). Age and BMI modified significantly this risk when analyzed independently (HRage = 2.02 [95% CI: 1.12-3.64], HRBMI = 0.5 [95% CI: 0.29-0.88]) but were excluded from the model due to its high correlation with smoking duration.

Conclusions: Markov chain modeling is a novel longitudinal and dynamic approach to stratify lung cancer risk. Our model demonstrated the benefits of incorporating risk factors like additional carcinogen exposure, and smoking duration to refine risk-based screening. External validation is needed to assess its role in optimizing screening, decision-making and patient participation before clinical implementation.

P1.04.40 Improving Lung Cancer Risk Prediction in Asbestos Exposed Individuals: The AQC Ensemble Model

C. Kumarasamy[1], K. Betts[1], R. Norman[1], S. Markowitz[2], F. Brims[1]
[1]Curtin University, Perth/AU ,[2]Queen's College, New York/NY/USA

Introduction: Lung Cancer (LC) screening effectiveness is dependent on selecting an appropriate high-risk population. Current risk models underestimate LC risk in asbestos exposed populations, by not accounting for the increased relative excess risk by interaction (RERI) between asbestos and tobacco exposure. The aim of this study was to develop a LC risk model for asbestos exposed populations using a machine learning approach, with external validation.

Methods: Training cohort: 3,258 individuals (162 LCs) from the United States City University of New York (Queen's College) Multisite Cancer Screening Program; External vValidation cohort: Western Australian Asbestos Review Program, 1,357 individuals (51 LCs). Both populations were similar with occupational asbestos exposure, male predominance and comprised mostly of former tobacco users. Variables for risk prediction included: age, sex, smoking duration, smoking intensity, time since quit smoking, education level, self-reported chronic obstructive pulmonary disease, personal history of cancer, family LC history and time since first exposure to asbestos (latency).We developed an ensemble machine learning model (AQC ensemble), combining a parametric logistic regression model and a non-parametric eXtreme Gradient Boosted Tree (XGBoost) model. All models were benchmarked against the PLCOm2012 risk model. AUC-ROC was the primary metric for comparison. The best performing parametric and non-parametric models were combined using Bayesian weighted averaging to generate the final AQC ensemble model's predictions.

Results: Logistic regression demonstrated similar predictive performance in validation (AUC: 0.7067; 95% CI: 0.6369 - 0.7765) over XGBoost (AUC: 0.7021; 95% CI: 0.6284-0.7758). The AQC ensemble model had stronger performance than both comprising models (AUC: 0.7123; 95% CI: 0.6408-0.7838), and the PLCOm2012 model (AUC: 0.6325; 95% CI 0.5432-0.7218). Mean calibration indicated that the AQC ensemble model was well calibrated in the US development cohort, but overestimated risk in validation cohort.Model interpretation using Shapley values indicated that smoking duration was the most impactful variable in the AQC model's predictions, with asbestos exposure latency being the fourth most impactful variable, closely followed by age.

Conclusions: The AQC model is the first LC prediction model to account for the RERI of asbestos and tobacco exposure and performs well in occupationally exposed populations. Given the widespread asbestos exposure in many countries and the resultant interaction of risk with tobacco exposure, the AQC's performance highlights a potential role for cohort specific models in LC screening selection. Further external validation is required.

Figure 1. ROC curves comparing the discriminative performance of the $PLCO_{m2012}$, the best performing Logistic Regression Model, the best performing XGBoost Model and the AQC ensemble model in predicting LC incidence in ARP validation cohort.

P1.04.41 Survival Differences Following Surveillance Detected Vs. Symptom Detected Recurrence in Patients With Lung Cancer

M. Hassing[1], T. Woolschot[1], N. Moss[1], M. van den Heuvel[1], L. van de Poll[2], C. van den Hurk[3], C. Verberkt[1], N. Billingy[1], A. Becker-Commissaris[4], I. Walraven[1]
[1]Radboudumc, Nijmegen/NL ,[2]Netherlands Cancer Institute, Amsterdam/NL ,[3]Catharina ziekenhuis, Eindhoven/NL ,[4]Amsterdam UMC, Amsterdam/NL

Introduction: Follow-up care for lung cancer patients consists of a one-size-fits-all surveillance method of thoracic CT-scans every six months. This routine follow-up can be a source of anxiety for patients, often lasting several weeks before the scheduled imaging. Moreover, literature shows that many patients who experienced a recurrence already had symptoms in retrospect. Currently, it is unclear if a surveillance method completely based on symptoms would result in different survival outcomes. Therefore, this study examined differences in overall survival (OS) after scheduled versus symptom-based surveillance in patients with lung cancer.

Methods: Data from the SYMPRO-Lung study were used to assess OS differences between surveillance-based versus symptom-based recurrence detection. In the SYMPRO-Lung study, the effect of patient-reported symptom monitoring on health-related quality of life and OS in stage I-IV lung cancer was assessed. The detection method of recurrences during follow-up (scheduled versus symptom) were extracted by the National Cancer Registry and was based on the review of radiology and electronic health record reports. Cox proportional hazards analysis was used to assess differences between scheduled versus symptom-based surveillance on OS, corrected for confounding. Sensitivity analyses were performed to assess OS differences in time to secondary recurrence. In all analyses, we adjusted for age, stage, histology, and treatment.

Results: A total of 444 patients were included of whom 244 (55%) patients developed a recurrence during median follow-up of 46 months. Of these, 181 (74%) recurrences were detected with scheduled follow-up and 63 (26%) were detected after patients contacted the hospital due to symptoms. No statistically significant differences in baseline characteristics were observed between the two groups. Median OS after first recurrence was 14.5 months (IQR: 6.2-28.1) in the surveillance-based group versus 10.4 months (IQR: 2.4-29.4) in the symptom-based group (p= 0.4). After correction for confounding, no significant differences were observed in OS (HR 1.18, 95%CI 0.85-1.63) (Figure 1) neither for time to secondary recurrence (HR 0.63, 95%CI 0.36-1.09).

Conclusions: No differences in OS were observed between patients in whom recurrences were detected via scheduled-based follow-up compared to patients in whom recurrences were detected via symptom-based follow-up. These results might indicate that a symptom-based surveillance strategy using patient-reported symptom monitoring may be as effective (and logistically less intensive) compared to the current one-size-fits-all scheduled surveillance strategy. Nonetheless, more research needs to be performed to validate these findings in larger cohorts.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.04.42 Circulating Tumor Cells Combined With Solid Nodular Ratio to Predict High-Risk Pathological Subtypes of Stage Ia Lung Adenocarcinoma

B. Rao[1,2,3], T. Chen[2], Y. Zhu[2], Q. Li[3], Y. Zhou[3], H. Li[1], Y. Huang[1]
[1]Zhujiang Hospital of Southern Medical University, Guangzhou/CN ,[2]Sun Yat-sen University First Affiliated Hospital, Guangzhou/CN ,[3]Sun Yat-sen University Cancer Center, Guangzhou/CN

Introduction: This study aims to analyze the relationship between circulating tumor cells (CTCs) and the clinical, imaging, and pathological characteristics of patients with stage pre-IA and IA lung adenocarcinoma. And to preliminarily explore the significance of CTCs detection in the surgical treatment.

Methods: A retrospective analysis was conducted on 130 cases diagnosed with pre-stage IA or stage IA pulmonary adenocarcinoma and 25 cases with benign pulmonary lesions, all treated by surgical resection from April 2018 to January 2021. All cases were solitary pulmonary nodules. Preoperative peripheral venous blood samples were collected from each patient for CTCs detection. Tumor cells were enriched using magnetic microparticle technology, and in situ fluorescence hybridization (FISH) was employed for identification and quantification. We compared the pathology and imaging features between CTCs-positive and CTCs-negative groups. Patients were categorized based on the degree of pathological infiltration. Univariate and binary logistic regression analyses were conducted, and Receiver Operating Characteristic curves were generated to develop a predictive model for identifying pathological subtypes of stage IA lung adenocarcinoma. Additionally, a three-year postoperative follow-up was performed to assess survival differences between groups, with Kaplan-Meier curves plotted.

Results: 1.Statistically significant differences were found between the CTC-positive and CTC-negative groups regarding patient age, lesion size, fluorodeoxyglucose (FDG) uptake, and the presence of high-risk pathological subtypes. No significant differences were observed in coagulation function or pulmonary tumor markers. Multivariate analysis revealed that with elevated FDG uptake were three times more likely to have CTCs. 2.No significant difference in CTCs positivity rates was noted between the adenocarcinoma in situ (AIS) group and the stage IA lung adenocarcinoma group. However, significant differences in CTCs positivity rates were found between the benign lesions and lung adenocarcinoma, as well as between groups with high-risk pathological subtypes. 3.Significant differences in CTCs positivity rates, smoking history, lesion size, FDG uptake levels, and consolidation/tumor ratio (CTR) were observed between groups with and without high-risk pathological subtypes. Notably, CTCs positivity and a CTR greater than 50% were identified as independent risk factors for high-risk pathological subtypes. The ROC curve analysis demonstrated a predictive AUC of 0.867 (95% CI: 0.783-0.952) for determining the presence of high-risk subtypes. 4.During the follow-up period, there were 2 cases of recurrence after radical surgery (1.54%), with 8 new lesions (6.15%) surgically removed. Patients with high-risk subtype were more likely to develop new lesions within three years post-surgery (p=0.04). No significant difference in three-year survival data was found between patients with preoperative CTC-positive status.

Conclusions: The metabolic activity in lesions of CTCs-positive patients may be higher than that in CTCs-negative lesions. A model combining CTC positivity and lesion solid ratio can accurately predict the presence of high-risk pathological subtypes in stage IA lung adenocarcinoma, offering valuable guidance for surgical approaches. Furthermore, patients with high-risk pathological subtypes may have an increased risk of requiring secondary surgeries within three years, while the predictive value of preoperative CTCs for survival outcomes appears limited.

P1.04.43 Evaluating the Role of Digital Tomosynthesis in Lung Cancer Screening: A Cost-Effective Alternative to Annual LDCT in Resource-Limited Settings

N. Triphuridet[1], S. Warittikoon[2]
[1]Princess Srisavangavadhana Faculty of Medicine, Chulabhorn Royal Academy., Bangkok/TH ,[2]Chulabhorn hospital, Chulabhorn Royal Academy., Bangkok/TH

Introduction: Annual low-dose computed tomography (LDCT) screening has been shown to reduce lung cancer mortality. However, the cost of implementing such programs may be prohibitive in resource-limited settings. Chest digital tomosynthesis (DT), a lower-cost imaging modality with high sensitivity and specificity for pulmonary nodule detection, may offer a viable alternative. Alternating LDCT with DT could maintain early detection rates while reducing overall screening costs.

Methods: In this 5-year prospective study, 634 high-risk individuals (current or former smokers with >30 pack-years), aged 50-70 years, were enrolled between July 2012 and January 2014 at Chulabhorn Hospital, Thailand. All participants underwent baseline LDCT (T0). Those with normal lung findings or stable lesions after two years were followed annually using alternating DT and LDCT. Participants with abnormal findings at any point received LDCT follow-up.

Results: A total of 634 participants underwent initial LDCT screening. Of these, 187 participants with normal baseline findings received DT at year 1 (T1), and 427 participants with stable lung findings after two years received DT at year 3 (T3). All participants received LDCT at years 2 and 4, with additional LDCT as needed based on findings. Lung cancer was diagnosed in 22 participants: 50% at stage I, 18.2% at stage II, 9.1% at stage III, and 22.7% at stage IV. The proportion of stage I lung cancer detected (50%) is comparable to prior randomized controlled trials using annual LDCT, which reported detection rates ranging from 36% to 63%.

Conclusions: A lung cancer screening protocol alternating DT with biennial LDCT demonstrated a similar proportion of stage I diagnoses as annual LDCT programs. In resource-limited settings, DT may be a practical and cost-effective alternative for early lung cancer detection.

P1.04.44 Clinical Efficiency of Repeat CT-Guided Transthoracic Needle Biopsy of Peripheral Lung Lesions

S. SAMSONIK[1], Y. Esakov[1]
[1]Oncology Centre No. [1] of the Yudin City Clinical Hospital of the Moscow City Health Department, MOSCOW/RU

Introduction: Transthoracic CT-guided needle biopsy (CT-TNB) of peripheral pulmonary nodules (PPN) is still method of choice for morphologic diagnosis verification nevertheless false negative and non-diagnostic results are often complicate decision process (the management of this patients). Hereby we present results of repeat biopsies of PPN with real life efficiency and sensitivity of the procedures.

Methods: In period from January 2022 to December 2024 CT-TNB was performed in 504 cases for 478 patients. Following primary non-diagnostic results repeat biopsy was done in 26 (5,16%, 95%CI: 3,54-7,45) patients with suspicion of primary lung cancer and metastatic disease in 32 and 10 cases respectively. All procedures were performed using 18G needles. Median age was 68 (63; 77) years (range 36 - 92 years) with male predominance 26/16. PPN's size distribution to less or more than 20 mm and GGO were as follows: 7, 18 and 1 respectively. Solitary and multiple nodules were presented in 25 and 17 cases respectively. 3 biopsies were performed under the stepwise approach, 8 with the SIRIO navigation system, 15 with CT fluoroscopy control.

Results: Morphologic results were obtained in 20 (76,1%) cases after repeat biopsies (95%CI: 57,95 - 88,97): small cell lung cancer (n=1), Adenocarcinoma (n=7), SCC (n=6), pulmonary fibrosis (n=1), non-differentiated carcinoma (n=1) and metastatic tumors (n=4) were established. Sensitivity, specificity and accuracy for repeat biopsies were 100%, 76,6% and 77,4% respectively. Treatment routing was monitored for 20 patients: Chemotherapy (n=5), CRT (n=2) and Surgery (n=13) were carried out. Follow up was proposed for 6 patients with repeated non-diagnostic results of which in 2 cases lesions were regressed during the first and after 12 month in 3 and 4 cases respectively, one patient was referred to chemo-radiation following strongly suspicion of local tumor recurrence without final confirmation after twice repeat biopsies.

Conclusions: Repeat biopsy of PPN after non-diagnostic results of CT-TTB is informative in more than 50% of cases and is indicated for patients with strongly suspicious of malignant tumor before start of the treatment.

P1.04.45 Multi-Center Validation of a Circulating 9-microRNA Signature for Lung Cancer Early Detection

E. Dama[1], R. Cuttano[1], K.M. Afanga[1], N. Di Cillo[1], V.S. Nair[2], R. Dziadziuszko[3], T. Dandekar[4], P. Widlak[3], W. Rzyman[3], G. Veronesi[5], F. Bianchi[1]
[1]Fondazione IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo/IT ,[2]Fred Hutchinson Cancer Center, Seattle/WA/USA ,[3]Medical University of Gdańsk, Gdańsk/PL ,[4]University of Würzburg, Würzburg/DE ,[5]IRCCS San Raffaele Scientific Institute, Milan/IT

Introduction: Lung cancer remains the leading cause of cancer-related deaths worldwide. Low-dose computed tomography (LD-CT) screening is effective, and combined with effective minimally invasive molecular testing such as circulating microRNAs (c-miRs), it has the potential to further reduce the burden of lung cancer. However, the clinical application of c-miRs requires further validation across diverse patient cohorts from different countries.

Methods: In this study, we present a plasma signature of 9 c-miRs derived from a robust multi-platform workflow with a multi-center design (Figure 1). We first analyzed publicly available c-miR datasets from 150 lung cancer (LC) patients and 136 non-cancer controls (STEP-1), identifying 321 shared c-miRs. Using RankProd meta-analysis, we found 45 differentially expressed c-miRs. We then validated these 45 c-miRs in a case-control cohort of plasma samples form 54 LC patients and 54 non-cancer controls (STEP-2). Next, we cross-checked intracellular expression of c-miRs in 173 LC cell lines to support specificity and assessed their impact on LC risk (STEP-3). We finally analyzed plasma samples from a total of 72 LC and 261 non-cancer controls from two European LD-CT screening cohorts (Medical University of Gdańsk, Gdańsk, Poland; Humanitas Clinical and Research Center, Milan, Italy) to refine a validate the plasma 9 c-miRs signature (STEP-4).

Results: The classification performance of the signature was high in the two screening cohorts, with an AUC of 0.78 (Sens 0.76; Sp 0.67; Accuracy 0.70), and an AUC of 0.75 (Sens 0.82; Sp 0.68; Accuracy 0.71) in the Polish and Italian cohorts, respectively. The diagnostic accuracy of the signature was independent and not influenced by age, gender, smoking (status and intensity), nodule size, and density. Additionally, the signature detected stage I lung cancer, with an AUC of 0.76 (95%CI: 0.68-0.84) and 0.69 (95%CI: 049-0.89) in the Polish and Italian cohorts respectively and a predictive ability of 0.63-73. Finally, the signature discriminated benign from malignant nodules with an AUC of 0.71 (95%CI: 0.58-0.84).

Conclusions: The proposed panel of nine circulating miRNAs serves as a robust and precise diagnostic tool, which could further improve effectiveness of LD-CT screening program. We plan to validate our signature in a cohort of 277 patients at the Fred Hutchinson Cancer Center in the U.S. This extensive validation of our c-miR-based test in screen-detected tumors across multiple, independent cohorts highlights the uniqueness of our study and further supports its clinical utility.

P1.04.46 Predicting Malignancy in Ground-Glass Opacity Using Multivariate Regression and Deep Learning Models: A Proof-Of-Concept

A. Agbarya[1], D. Levy Faber[2], M. Pincas[3], E. Sabo[2]
[1]Bnai Zion MC, Haifa/IL ,[2]Carmel Medical Center, Haifa/IL ,[3]Technion, Israeli Institute of Technology, Haifa/IL

Introduction: Background: Ground-glass opacification (GGO) refers to areas of increased lung opacity on computed tomography (CT) scans. Distinguishing malignant from benign lesions using CT remains a significant challenge. This study aims to apply a multivariate statistical regression model and deep learning methods based on pixel features extracted from CT scans to predict malignancy and compare the performance of these two models.

Methods: This retrospective study included 72 patients from Carmel Medical Center who had GGOs. Of these, 46 patients met the criteria for pure GGO, as defined by two independent radiologists. After manually segmenting the GGOs on the CT scans, pixel features were extracted using the MaZda software package, which analyzes six different image texture features. These textural variables were then used as input for the multivariate statistical regression model. Additionally, a deep learning model, developed by our group and hosted on the cloud, was applied using the CT images containing the GGOs.

Results: Among the 46 patients, 35 were diagnosed with malignant lesions and 11 with benign findings. Using the multivariate statistical regression model, we identified 26 variables with significant or near-significant differences through univariate analysis. In subsequent multivariate analysis, two independent variables were identified: S(4,4)AngScMom (p = 0.012) and WavEnLH_s-2 (p = 0.008). The formula based on these two variables yielded a sensitivity of 91% and specificity of 67%. The deep learning model demonstrated a sensitivity of 100% and specificity of 80%.

Conclusions: This proof-of-concept study demonstrates the superior performance of the deep learning model compared to the multivariate statistical regression model, particularly in terms of sensitivity and specificity. However, given the small sample size, these results could potentially improve with larger patient cohorts.

Introduction: Lung cancer (LC) is one of the most common malignant cancers worldwide representing the leading cause of death. Tobacco smoking is the main aetiological factor in lung carcinogenesis, but long-term exposure to air pollution and genetic susceptibility may play a role. In the last few decades , the diagnosis and therapies of LC have shown great improvement, but its clinical management is still challenging due to diagnosis mainly at advanced stages. Thus, there is an ever-increasing need to develop innovative, easy-to-use, and non-invasive diagnostic methodologies to implement within large-scale screening protocols to enable early detection and improve the management and clinical outcome . Recently, the volatile organic compounds (VOCs) analysis in exhaled breath, known as breathomics, has showed to be promising to identify disease-specific metabolic signatures. In this study, we analysed breath samples to detect and characterize by deep learning the breath fingerprint of patients with lung cancer.

Methods: 195 participants were recruited : 114 patients affected by LC and 81 healthy controls (HC). The method is based on sampling of end-tidal breath directly onto two-bed adsorbent cartridges (Biomonitoring steel tubes, Markes International) by means of automated sampler Mistral (Predict srl). Ambient air samples (AA) were collected at each sampling . Breath samples were thermally desorbed (Unity Ultra-xr Markes) and analysed by Gas Chromatography/Mass Spectrometry (GC Agilent 7890/MS Agilent 5975). Ion channels were acquired across a mass-to-charge (m/z) range from 35 to 250 with unit mass resolution. The instrument operated at a scanning frequency of approximately 3.31 Hz, resulting in around 8805 retention time (RT) points over a period of 44 minutes. Each sample was represented by a matrix dimension of R × 216, where R ≈ 8805. . All experimental temporal scans have been preprocessed using Gaussian smoothing and Savitzky-Golay filtering to increase the signal-to-noise ratio. To reduce the huge amount of experimental data, for each subject, the 216x8805 preprocessed data points have been converted into 2D images in which each pixel is associated with a (m/z, RT) pair and whose color depends on the intensity of the chromatogram signal. Subsequently, these 2D images have been embedded in an Artificial Intelligence workflow to implement a classifier that can distinguish between patients with LC and healthy controls.

Results: A preliminary classification of the images using Decision Tree, Random Forest, and Convolutional Neural Network (CNN) algorithms, performing a 10-fold repeated 5-fold cross-validation, was obtained. The best results have been achieved with CNNs, with both a mean AUC and a balanced accuracy over 0.90 within errors over the 100 iterations of the workflow.

Conclusions: The proposed models demonstrated superior performance compared to conventional expert-driven methodologies, enabling more accurate and efficient classification between healthy individuals and patients with lung cancer, while maintaining high specificity. These findings highlight the potential of this data-driven approach to advance breath-based diagnostic strategies by improving group differentiation, optimizing analytical processes, and facilitating scalable and cost-effective implementation in clinical practice.

P1.04.48 Rapid Intra-Operative Detection of Visceral Pleural Invasion in Non-Small Cell Lung Cancer Using Label-Free Multiphoton Microscopy

S. Chen, J. Zhou
Peking University People's Hospital, Beijing/CN

Introduction: Visceral pleural invasion (VPI) constitutes a significant pathological factor in non-small cell lung cancer (NSCLC). The rapid and accurate intraoperative assessment of VPI might be important for determining the appropriate extent of surgical intervention and may contribute to improved disease-free and overall survival rates. However, current intraoperative diagnostic methods for VPI lack reliability. Multiphoton microscopy (MPM) offers promise due to its label-free imaging capabilities and potential for in vivo applications. Therefore, this study aims to investigate the potential of label-free MPM for imaging lung cancer tissues, pleura, and the status of VPI.

Methods: This study analyzed 83 formalin-fixed paraffin-embedded NSCLC specimens, each containing both tumor regions and adjacent pleural tissues. Specimens were stratified by VPI status according to Hammar grading criteria: PL0 (no invasion, n=50), PL1 (elastic layer penetration, n=25), and PL2 (full-thickness pleural infiltration, n=8). Each specimen was sectioned into two serial 10-μm-thick slices: one underwent label-free multiphoton microscopy (MPM) capturing TPEF/SHG signals, while the adjacent slice received Elastica van Gieson (EVG) staining.A board-certified thoracic pathologist first delineated regions of interest (ROIs) containing tumor-pleural interfaces on EVG-stained sections. Two independent pathologists blinded to EVG results evaluated elastic layer integrity and tumor infiltration patterns in MPM datasets, classifying cases into PL0/PL1/PL2 categories. Diagnostic accuracy was calculated by comparing MPM-based assessments with gold-standard EVG-determined VPI status.

Results: Our study systematically validated the diagnostic potential of MPM in visualizing pleural elastic architecture and tumor invasion. The figures present MPM images of lung tissues alongside their corresponding EVG-stained images. MPM-based two-photon excited fluorescence (TPEF) demonstrated high specificity for elastin fibers within pleural tissues. As shown in Figure(B), TPEF signals (color-coded red) exhibited precise correspondence with EVG-stained elastic fibers (yellow regions). The dense, curvilinear architecture of elastic fibers in visceral pleura was clearly delineated by MPM without exogenous labeling.Furthermore, lung cancer cells were identified via intrinsic TPEF signals from NADH and FAD, exhibiting bright cytoplasmic fluorescence and non-fluorescent nuclei (pink regions). In conclusion, MPM effectively visualized the relationships between cancer cells and the visceral pleura elastic layer and parietal pleura, providing equivalent identification capability to EVG staining.

Conclusions: Our findings demonstrate that MPM technology can rapidly and accurately detect VPI in lung cancer. This capability may assist thoracic surgeons in making quick intraoperative decisions regarding the extent of the surgery for patients.

P1.04.49 Targeting VEGFR3 Nir Fluorescent Probe for Identification of NSCLC Metastatic Lymph Nodes an Exploratory Study on Surgical Navigation

H. Zhou[1], H. Wang[1], H. Qiu[1], H. Li[1], S. Li[1], L. Yao[1]
[1]Department of Thoracic Surgery, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou [510080], China., Guangzhou/CN

Introduction: Lymph node metastasis in non-small cell lung cancer (NSCLC) significantly impacts prognosis, yet current imaging modalities (CT/PET-CT) lack sensitivity for micrometastases. VEGFR3, a key regulator of lymphangiogenesis, is overexpressed in metastatic NSCLC, offering a molecular imaging target. This study developed a VEGFR3-targeted NIR-II fluorescent probe (VEGFR3-ICG) to enhance intraoperative identification of metastatic lymph nodes (LNs), leveraging NIR-II imaging's superior tissue penetration (8mm vs. NIR-I 6mm) and high signal-to-noise ratio.

Methods: VEGFR3-ICG was synthesized by conjugating a VEGFR3-specific peptide (NH2-CGLARGRGC) with indocyanine green (ICG) via solid-phase synthesis. Purity and structure were validated by HPLC and mass spectrometry. Optical properties were assessed via absorption/emission spectra and tissue penetration assays. Cytotoxicity was evaluated in HUVECs and NSCLC cell lines (LLC, A549, H1703) using CCK-8 and acute toxicity tests in mice. VEGFR3 expression was confirmed by Western blot, and probe uptake was analyzed via flow cytometry. Subcutaneous tumor and LN metastasis mouse models were established for in vivo imaging, with tumor/background ratio (TNR) and positive/negative LN ratio (PNR) quantified. NIR-II-guided surgical resection was performed, followed by histopathological validation. Human NSCLC specimens were incubated with the probe for ex vivo imaging correlation.

Results: The VEGFR3-targeted NIR-II probe VEGFR3-ICG demonstrated high specificity and safety in NSCLC applications. With a penetration depth of 8 mm (NIR-II) and spatial resolution of 58-59 μm (FWHM), it achieved superior optical performance compared to conventional NIR-I imaging. At 20 μM, cell viability exceeded 90% in NSCLC cell lines (A549, LLC, H1703), and acute toxicity studies in mice confirmed no significant biochemical or histopathological abnormalities. VEGFR3 expression in NSCLC cells was 3.2-fold higher than in HUVECs ($P<0.01$), driving a 40% increase in probe uptake versus non-targeted ICG ($P<0.05$). In vivo, VEGFR3-ICG exhibited a tumor/background ratio (TNR) of 5.704 in A549 tumors and a positive/negative lymph node ratio (PNR) of 2.224 in metastatic lymph nodes (both $P<0.01$ vs. ICG). Clinical validation using ex vivo human NSCLC specimens revealed strong concordance between TNR/PNR and histopathology ($P<0.01$), confirming its diagnostic accuracy for metastatic LN identification.

Conclusions: VEGFR3-ICG is a novel NIR-II probe with high specificity, safety, and translational potential. It enables precise intraoperative identification of NSCLC metastatic LNs, addressing the limitations of conventional imaging. This technology may revolutionize LN dissection strategies and improve surgical outcomes.

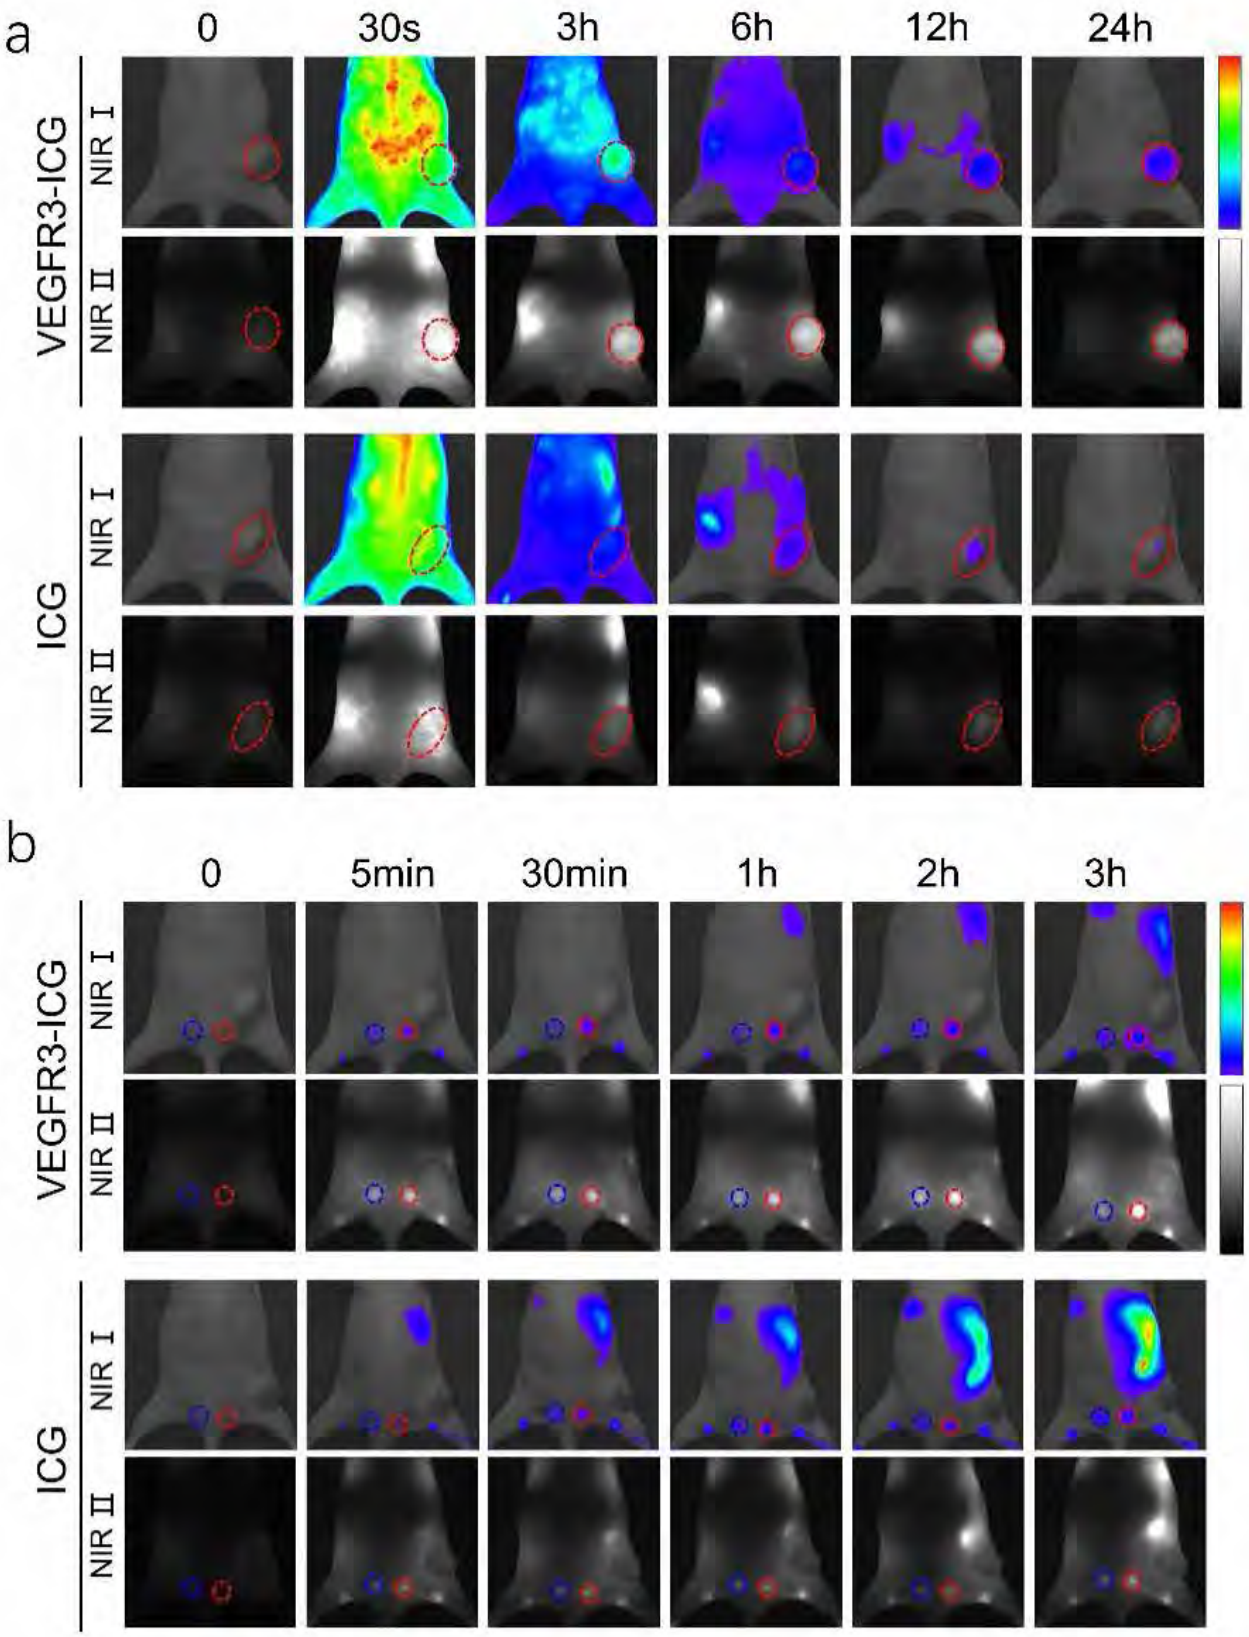

Figure 1. VEGFR3-ICG enables precise identification of Tumor and metastatic lymph nodes. a. NIR I/II imaging of A549 tumor-bearing mice after intravenous injection of ICG and VEGFR3-ICG; b. P1.04.50 Fluorescein-Free Confocal Laser Endomicroscopy for Intraoperative Diagnosis of Pulmonary Nodules: A Comparative Study With Frozen Section

J. Xie, L. Mao, Y. Rong, S. Lu, Y. Liu, Y. Lin, K. Luo
Sun Yat-sen University Cancer Center, Guangzhou/CN

Introduction: Since low-dose CT (LDCT) screening has increased detection of sub-centimeter pulmonary nodules, 10-20% of indeterminate lesions still require invasive procedures for definitive diagnosis. Current intraoperative frozen section (FS) analysis faces challenges in traumatic biopsy and time delays (30-45 minutes processing). This study aimed to evaluate a novel fluorescein-free confocal laser endomicroscopy (CLE) system for real-time intraoperative diagnosis during minimally invasive thoracic surgery.

Methods: Prospective analysis of consecutive patients undergoing VATS resection for radiologically indeterminate nodules at a tertiary thoracic center. Resected specimens underwent systematic ex vivo CLE imaging with standardized protocol: 1) Anatomical orientation 2) Dual-region scanning (lesion-normal interface) 3) 10-field video capture (>20 seconds recording). Two blinded thoracic pathologists evaluated cellular features using validated criteria. Pathological subtype evaluation was also predicted synchronously. Subsequent intraoperative FS evaluation was performed on the same nodules. According to paraffin section, the diagnostic performance of CLE was compared with preoperative CT and FS.

Results: All procedures were successfully completed without fluorescein, yielding high-quality video data from all 44 nodules (39 malignancies, 4 inflammatory lesions, 1 benign tumor) with no adverse events. CLE demonstrated 93.2% diagnostic accuracy (38/41) malignancies with 97.4% sensitivity and 60% specificity. Compared to preoperative CT, CLE is significantly better than conventional CT (70.5%, $p<0.01$), In 5/44 (11.4%) FS-indeterminate cases, CLE provided definitive diagnoses concordant with final histology. Real-time pathological subtyping was achieved in 28/41 (68.3%) cases.

Conclusions: In this first-in-human study, Fluorescein-free CLE was implemented as a real-time adjunct to FS analysis which provided comparable diagnostic accuracy. The potential advantage of CLE intraoperative diagnosis for patients with early-stage lung cancer lies in the resolution of FS uncertainties and the enabling of immediate histologic subtyping. Further multicenter studies are needed to establish a CLE-guided decision-making procedure for precision thoracic surgery.

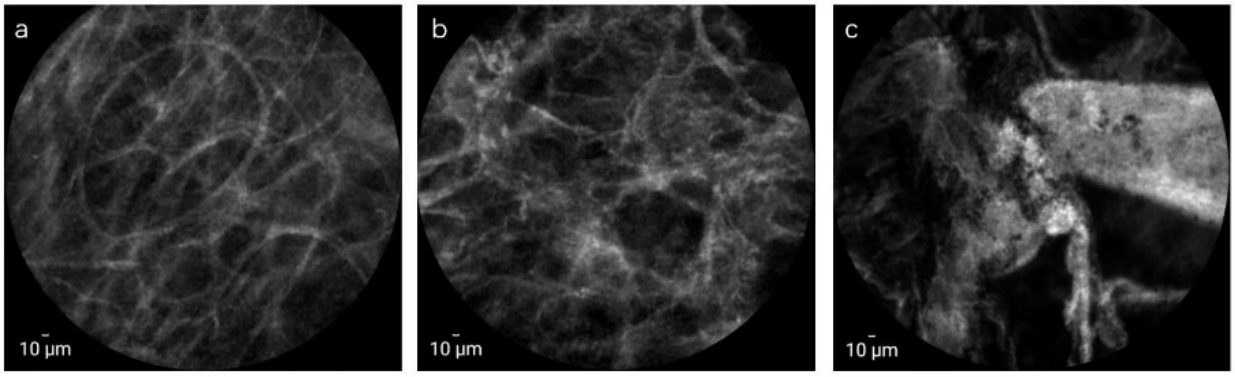

Figure 1: (a) **Normal lung tissue :** Alveolar structure is regular and uniformly sized. The alveolar wall, composed of a single epithelial layer, shows uniform thickness with a smooth surface and no notable tortuosity or thickening.(b) **Malignant nodules :** It exhibit collapsed alveolar structures with thickened, tortuous walls, marked architectural disorganization in surrounding tissue, and aggregated high-signal cell clusters.(c) **Benign nodules :** Alveoli display smooth epithelium and uniformly thin walls without thickening/tortuosity, surrounded by homogeneous tissue with patchy fibrin deposits and no atypia.

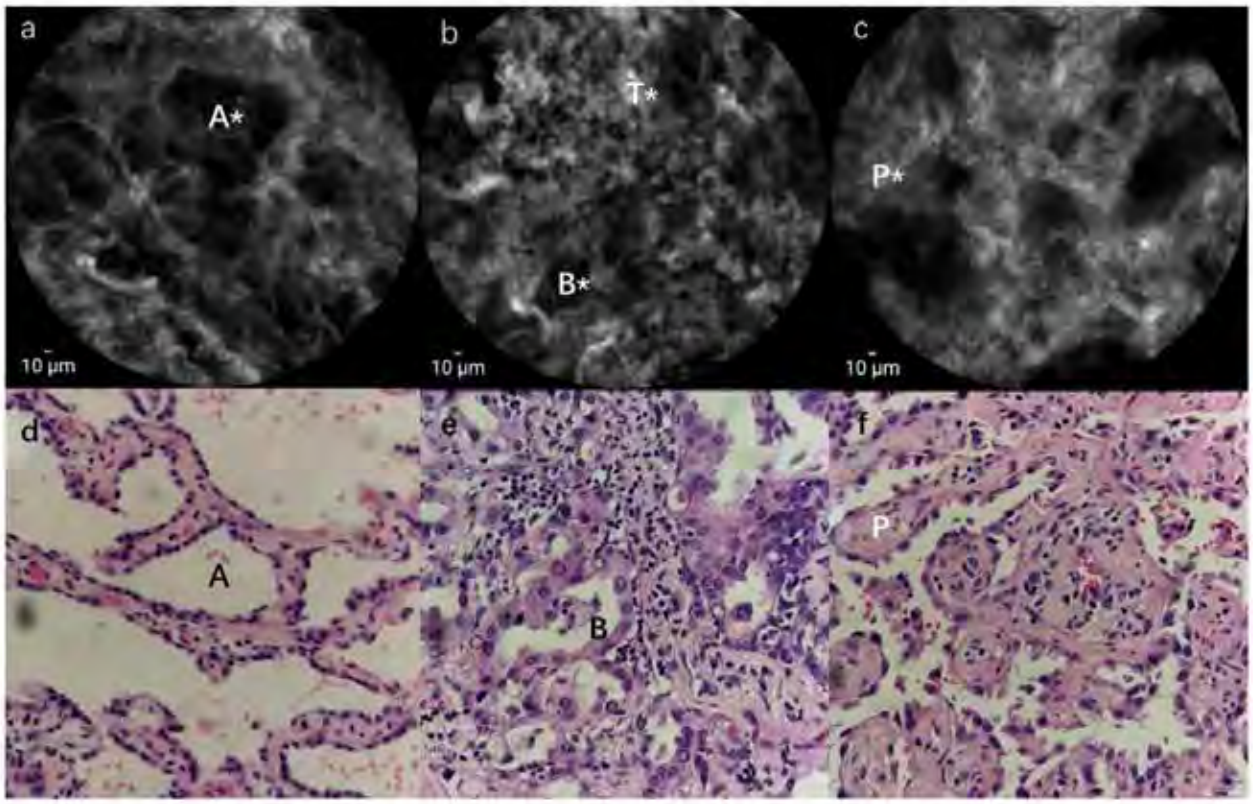

Figure2 : (a、d) **Minimally invasive adenocarcinoma:** CLE and paraffin sections showed collapsed alveoli (A/A*) with mildly thickened walls featuring atypical heterotypic cells and high-signal cell clusters, yet preserved alveolar structure. (b、e) **Acinar-predominant adenocarcinoma:** Tumor infiltrates alveoli, showing high-signal cell clusters (T*) and diagnostic low-signal acinar cavities (B*), that confirm acinar structures(B). (c、f) **Papillary-predominant adenocarcinoma:** CLE shows medium-signal papillary patterns (P/P)* with cell clusters and characteristic peripheral low-signal zones, diagnostic of papillary-predominant adenocarcinoma.

Introduction: Lung cancer screening with low-dose chest CT enhances early detection but comes with high costs and radiation exposure. Moreover, radiological screening for NSCLC primarily targets smokers, leaving non-smokers with limited screening options. Although early diagnosis is crucial, it often occurs at advanced stages. While immunotherapy (IO) holds promise, its long-term benefits are limited to certain patients. Cough, a common symptom of lung cancer, gained attention as a digital biomarker for lung-related diseases during the COVID-19 pandemic. However, its potential remains largely untapped in the NSCLC landscape. The I3LUNG project (NCT05537922) explores AI-based cough analysis as a non-invasive method to distinguish NSCLC patients on IO from healthy individuals. Using machine learning, we aim to develop an accessible, cost-effective pre-screening tool to enhance detection and complement radiological methods.

Methods: Cough recordings were collected from 91 stage IIIB-IV NSCLC patients undergoing IO and 109 healthy individuals, forming a dataset of 200 samples. Preprocessing steps included background noise removal and automatic cough segmentation. An early-fusion multimodal approach was implemented. A total of 39 acoustic features in the temporal and frequency domains were extracted. Then, the set of features was enriched with embeddings extracted from a convolutional neural network (CNN) trained on MFCC-based spectrograms. These embeddings were then reduced in dimensionality using Principal Component Analysis (PCA) while preserving 98% of their variance. The dataset was split into 60% training, 30% validation, and 10% testing. Feature selection was performed using LASSO, and a Support Vector Machine (SVM) classifier was optimized via grid search with a hold-out method. To evaluate performance, three models were compared: a unimodal SVM (acoustic features only), a unimodal CNN classifier (MFCC-based spectrograms only), and an early fusion multimodal model combining acoustic features and CNN-extracted embeddings.

Results: The unimodal SVM model achieved an F1-score of 71%, sensitivity of 73%, and specificity of 69%. The unimodal CNN performed better, with an F1-score of 86%, sensitivity of 100%, and specificity of 75%. The early-fusion multimodal approach, integrating acoustic features and deep learning-based embeddings, outperformed both, reaching an F1-score of 95%, sensitivity of 100%, and specificity of 92%.

Conclusions: Although the analysis was conducted in a limited sample of patients with advanced disease, the multimodal approach yielded the best performance among tested scenarios, highlighting its promise for future research into cough as a biomarker. This method could serve as a non-invasive, accessible, and cost-effective pre-screening tool with the potential to complement existing low-dose CT radiological screening programs. Cough-based technologies can offer economic sustainability and easy access, potentially extending pre-screening efforts to broader populations such as non-smokers or individuals exposed to air pollution who are currently underserved by traditional screening methods. By addressing risk factors beyond smoking, this approach could support the development of more inclusive and economically sustainable screening programs applicable also in rural and low-income countries, toward democracy of cure and reduction of inequalities.

P1.04.52 A Clinically Applicable and Generalizable Deep Learning Model for Segmenting Anterior Mediastinal Tumors Across Multiple Institutions

H. Watanabe[1], M. Miyake[1], K. Kobayashi[2], C. Takemura[1], A. Urikura[1], Y. Goto[1], Y. Yatabe[1], S-i. Watanabe[1], M. Kusumoto[1], R. Hamamoto[2]
[1]National Cancer Center Hospital, TOKYO/JP ,[2]National Cancer Center Research Institute, TOKYO/JP

Introduction: Anterior mediastinal tumors, such as thymoma and thymic carcinoma, are rare entities that pose substantial diagnostic challenge due to their low incidence and distinctive radiological features. Accurate pre-treatment diagnosis is essential for effective treatment planning and prognostic assessment. While computed tomography (CT) remains the cornerstone for imaging evaluation, interpretation often demands substantial expertise and experience. Recent advances in artificial intelligence (AI), especially deep learning (DL) algorithms, have shown significant potential for improving the diagnostic accuracy and efficiency of medical image analysis. However, developing deep learning models for rare diseases is inherently challenging due to limited large-scale datasets. Although a few segmentation models for anterior mediastinal tumors have been proposed, no prior studies have validated them across multiple institutions and clinically robust and generalizable models remain lacking.

Methods: This study was a retrospective observational analysis utilizing CT images acquired from multiple institutions. Institutional Review Board approval was obtained from the National Cancer Center of Japan (IRB 2023-229). No-code AI platforms allow model development without the need for specialized programming skills. Using such a platform, we developed a clinician-driven model to segment pre-treatment tumors on multiple institutions CT images. A total of 711 chest CT images were collected between April 1, 2000 and March 31, 2024, from 123 hospitals. Each image was derived from a unique patient with pathologically proven anterior mediastinal tumors (339 males, 372 females). Of these, 485 images were used for training, 62 for internal testing, and 164 for external testing. A 3D U-Net-based segmentation model was trained on the training dataset and evaluated on both internal and external testing datasets. The external testing dataset comprised CT images from institutions not involved in model development or internal validation.

Results: Based on the reference standards provided by board-certified diagnostic radiologists, the trained model achieved average Dice scores of 0.864, precision of 0.906, and recall of 0.858 on the internal testing dataset. On the external testing dataset, it achieved average Dice scores of 0.823, precision of 0.856, and recall of 0.821, demonstrating consistent performance across institutions.

Conclusions: We developed a clinically relevant segmentation model for anterior mediastinal tumors on multiple institutions CT images using a no-code AI platform. Our cohort included an external test set of 164 patients from 123 institutions, highlighting the broad applicability of the model. This study is the first to demonstrate robust and generalizable performance of a segmentation model for anterior mediastinal tumors, addressing the data scarcity challenge for such rare diseases.

P1.04.53 Potential for AI as First Reader in Lung Cancer Screening

R.E. Ledda[1,2], C. Valsecchi[1], F. Sabia[1], G. Milanese[2], M. Balbi[3], L. Rolli[1], M. Ruggirello[1], N. Sverzellati[2], A.V. Marchianò[1], U. Pastorino[1], G. Leuzzi[4]
[1]Fondazione IRCCS Istituto Nazionale dei Tumori, Milan/IT ,[2]University of Parma, Parma/IT ,[3]University of Turin, Turin/IT ,[4]IRCCS ISTITUTO NAZIONALE TUMORI FOUNDATION, Milan/IT

Introduction: To assess the agreement between human and AI readings for low dose CT (LDCT) outcomes according to Lung Reporting And Data System (LungRADS); to test the safety of using AI as first reader in lung cancer screening (LCS).

Methods: This retrospective analysis included 4104 volunteers from the BioMILD trial (ClinicalTrials.gov Identifier: NCT02247453). The baseline LDCTs, prospectively read by an experienced radiologist and classified into "negative" (categories 1 and 2 as per LungRADS v1.1) and "positive" (categories 3 and 4), were retrospectively analyzed by an AI software for LungRADS category assignment. The diagnosis of lung cancer (LC) at 2 years from baseline was used as reference standard to test the performance of human and AI readings. Agreement for LungRADS categories between human and AI readings was measured by the k-Cohen Index with Fleiss-Cohen weights (Kw) with 95% Confidence Interval (CI). Performance of human and AI readings was tested for diagnostic accuracy.

Results: The agreement between human and AI readings for negative and positive LDCTs was 83.5% (Kw 0.47; 95%CI: 0.43-0.50) (Table). Among 4104 participants, 68 were diagnosed with LC within 2 years from baseline. For 6 of them, LDCT was classified as negative by AI, but only 1/6 had been classified as positive by human reading (small cell carcinoma, stage IV). Sensitivity and specificity were 91.2% and 75.7% for AI, and 89.7% and 90.0% for human reading. The PPV and NPV were 6.0% and 99.8% for AI, and 13.1% and 99.8% for human reading. The expected reduction in LDCT reading when using AI as first reader is 74.7% (Figure).

Conclusions: Results demonstrated a moderate agreement between AI and human readings and that AI might be safely used as first reader in LCS.AI software was used for LDCT reading (AVIEW, Coreline Soft, Seoul, Korea) and for creating the figure (ChatGPT).

LungRADS Human reading	LungRADS AI reading		
	1-2	3-4	Total

P1.04.54 Breath-based Lung Cancer Detection: Initial Phase 2 Results for D5-Ethyl-β-D-glucuronide (OWL-EVO1) as a Lung Cancer Probe

E. Jackson[1], V. Singh[1], R. Smith[1], J. Mizen[1], L. Harlow[1], A. Michael[1], M. van der Schee[1], B. Boyle[1], M. Allsworth[1], P.A. Crosbie[2], E. Mishra[3], E. Caruana[4], I. Horvath[5], M. Drosslerova[6], L. Succony[7], R.C. Rintoul[8]
[1]Owlstone Medical, Cambridge/GB ,[2]The University of Manchester, Manchester/GB ,[3]Norfolk and Norwich University Hospital, Norwich/GB ,[4]Leicester Royal Infirmary, Leicester/GB ,[5]University of Debrecen, Debrecen/HU ,[6]Thomayer Hospital, Prague/CZ ,[7]Royal Papworth Hospital, Cambridge/GB ,[8]University of Cambridge, Cambridge/GB

Introduction: Low-dose CT (LDCT) screening for lung cancer has demonstrated mortality benefits but is hampered by low uptake. Breath analysis offers a solution as a non-invasive method for early lung cancer detection. The aim is utility within primary care or a home setting, as an adjunct to CT, to improve compliance with screening. Previous breath-based analyses, focusing on endogenous VOCs, were hindered by high variability and low signal-to-noise ratios. An engineered Exogenous Volatile Organic Compound (EVOC®) probe, with a bespoke analytical approach, has potential to improve both sensitivity and specificity of the breath-biopsy method. We have previously presented in-human safety, tolerability and proof-of-principle data using an IV EVOC® probe, D5-Ethyl-β-D-glucuronide (OWL-EVO1), for targeting extracellular β-glucuronidase for the detection of lung cancer through exhaled D5-ethanol on breath [1]. Here, we present initial findings of a case-control phase 2 study of OWL-EVO1 as an EVOC® probe for the detection of lung cancer, in participants with biopsy-proven lung cancer and co-morbidity/risk factor matched controls.

Methods: The primary endpoint was to report diagnostic accuracy (e.g. sensitivity and specificity) of intravenous (IV) OWL-EVO1 and secondary endpoints included finalising a protocol of optimised testing parameters and further profiling safety and tolerability (through adverse event reporting). Up to ten breath samples from pre-dose to 180min post dose, were collected from 187 patients with lung cancer (all stages), or controls, across seven sites and analysed using gas-chromatography mass-spectrometry.

Results: Breath samples using 2mg/kg doses of OWL-EVO1 (40 cases vs 47 controls) showed no case-control separation at early time points, with modest performance at later timepoints; likely compounded by off-target cleavage. To minimise off-target cleavage, the final optimised protocol included lowering the dose to 0.8mg/kg (50 cases vs 50 controls). Initial optimum performance for stage 1 and 2 lung cancer in this cohort was a 67% sensitivity and 70% specificity for breath samples taken at 130 minutes post-dose. Additionally, in this cohort a reduction in cleaved reporter signal was observed in patients recalled post-lung cancer treatment, at 130 minutes post-dose. There were 29 adverse events; 10 (in 6 participants) were possibly or probably related to OWL-EVO1 and resolved without sequelae. There were no serious adverse events or reactions, or suspected unexpected serious adverse reactions.

Conclusion: This study presents initial diagnostic accuracy data for IV OWL-EVO1 and supports further development of OWL-EVO1 as a probe to diagnose lung cancer using breath. Future work will utilise an inhaled form of OWL-EVO1 allowing for more practical administration in an out-of-hospital setting. The aim is to deliver higher probe concentrations to the tumour site, thereby reducing off-target cleavage to improve sensitivity and test performance.

P1.07.01 Wearable-Based Evaluation of Tubeless Thoracic Surgery for Early-Stage Lung Cancer

R. Wang[1], W. Guo[2], H. Huang[2], S. Xie[2], Y. Li[2], K. Chen[3], R. Li[2], Y. Chen[2], J. He[1], H. Liang[1]
[1]China State Key Laboratory of Respiratory Disease & National Clinical Research Center for Respiratory Disease, the First Affiliated Hospital of Guangzhou Medical University, Guangzhou/CN ,[2]the First Affiliated Hospital of Guangzhou Medical University, Guangzhou/CN ,[3]Shanghai CinoCore Health Technology Co Ltd, Shanghai/CN

Introduction: Although tubeless thoracic surgery has demonstrated superiority over intubated thoracic surgery, limited research has objectively evaluated its clinical utility. Recent advances in wearable devices and electronic patient-reported outcomes (ePROs) provide more comprehensive, multi-dimensional assessments of surgical outcomes. This prospective, real-world study integrated multimodal digital data to objectively assess the efficacy and clinical utility of tubeless thoracic surgery.

Methods: We prospectively enrolled lung cancer patients underwent thoracic surgery between March 2023 and December 2023. All patients wore wearable devices during hospitalization to record key vital sings. In addition, standardized questionnaires were used to collect ePROs covering nine symptoms. Propensity score matching (PSM) was applied to balance baseline characteristics and multimodal data were compared between tubeless group and intubated group.

Results: 263 patients were included in this study. After PSM, 80 patients were included in each group. Compared with the intubation group, the tubeless group exhibited significantly better postoperative outcomes, including shorter hospital stays (2.78 vs. 3.91 days, $p < 0.001$), reduced chest tube duration (0.93 vs. 2.26 days, $p < 0.001$), and lower chest tube drainage volume (128.90 vs. 313.88 mL, $p < 0.001$). ePROs further indicated significantly less pain, coughing, shortness of breath, and distress in the tubeless group, while wearable device measurements showed improved body temperature, heart rate, blood oxygen saturation, and sleep quality.

Conclusions: Tubeless thoracic surgery significantly improves perioperative outcomes in early-stage lung cancer. Integrating wearable devices and ePROs supports broader adoption and iterative refinement, ultimately enhancing patient recovery and quality of life.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.07.02 Septum-Guided Segmentectomy vs Lobectomy for Deeply Located cT1abN0M0 Non-Small Cell Lung Cancer

Q. Wang[1], J. Geng[2]
[1]Shanghai Chest Hospital, Shanghai/CN ,[2]Shanghai Chest Hospital, Shanghai City/CN

Introduction: While segmentectomy emerges as a lung-preserving alternative to lobectomy for early-stage non-small cell lung cancer (NSCLC), its application to deeply located tumors (inner two-thirds) remains controversial due to conventional margin-dependent paradigms. The septum-guided segmentectomy concept - utilizing intersegmental septa as anatomical barriers - offers a novel approach for these challenging lesions.

Methods: This retrospective study analyzed 407 patients with cT1abN0M0 NSCLC located in the inner two-thirds of the lung parenchyma who underwent either uniportal video-assisted thoracoscopic surgery (VATS) septum-guided segmentectomy or lobectomy between January 2019 and August 2024. After applying inclusion criteria and propensity score matching (PSM), 302 patients (before PSM) and 196 matched patients (after PSM) were included in the analysis. Perioperative data, recurrence-free survival (RFS), and overall survival (OS) were assessed, with a median follow-up of 25.0 months.

Results: There were 6 cases of recurrences or deaths in the lobectomy group before PSM. Remarkably, no cases of recurrence or mortality occurred in the segmentectomy group during the follow-up period. No significant difference was observed in RFS or OS between the segmentectomy and lobectomy groups (p = 0.18 and 0.22 before PSM, p = 1 and 1 after PSM). Although segmentectomy was associated with longer operative times (128.98 vs. 91.88 minutes; p < 0.001), but all patients achieved R0 resection. Rates of perioperative complications, including prolonged air leakage and chylothorax, drainage time, and hospital stay were comparable between the two groups (all p > 0.05).

Conclusions: With uniportal VATS, septum-guided segmentectomy demonstrates equivalent efficacy versus lobectomy for deeply located cT1abN0M0 NSCLC, validating intersegmental septa as reliable oncological boundaries. This anatomical approach eliminates dependence on margin distances and provides reliable evidence for the establishment of new and improved standards for precision resection.

P1.07.03 Effectiveness of a Generalizable AI Based Automated Workflow Recognition Model in Multiple Approaches to Lung Resection

S. Ohtani, J. Samejima, T. Ogane, Y. Sasagawa, T. Miyoshi, Y. Matsumura, K. Tane, K. Aokage, M. Tsuboi
National Cancer Center Hospital East, Chiba/JP

Introduction: The application of artificial intelligence (AI) in surgery is expanding, particularly in surgical video analysis. Automated workflow recognition has potential applications in workflow optimization and surgical education. Developing a more generalizable AI model requires validation across different surgical approaches. While the feasibility of an automated workflow recognition model in totally thoracoscopic surgery has been reported, its accuracy across different approaches remains unclear.

Methods: This study compared the accuracy of an AI-based automated workflow recognition model for lung resection surgery using datasets from both completely video-assisted thoracic surgery (cVATS) and hybrid video-assisted thoracic surgery (hVATS) approaches. A total of 134 patients who underwent lung resection in 2023 were included, excluding multiple resection cases. Surgical workflows were annotated into five phases: Phase 1: Preparation, Phase 2: Resection Preparation, Phase 3: Specimen Removal, Phase 4: Completion of Thoracic Procedures, and Phase Ex: Extra-Thoracic Phase. Surgical videos were extracted at one frame per second, and an AI-based automated workflow recognition model was developed using Swin Transformer. Model accuracy was validated, including an additional analysis using a dataset where the number of hVATS cases or sampled frames was adjusted to match cVATS.

Results: The study included 74 males and 60 females (median age: 70 years, 74 cases of primary lung cancer). There were 102 hVATS and 32 cVATS cases, with 783,034 frames analyzed. The F1 scores for cVATS, hVATS, and the entire dataset were 0.78, 0.84, and 0.83, respectively. The highest positive predictive values for each phase were 0.82, 0.77, 0.82, 0.82, and 0.93 for Phases 1, 2, 3, 4, and Ex, respectively. The best-performing model was the full dataset model validated with cVATS data (F1 score = 0.84). The F1 scores for cVATS and hVATS datasets were 0.78 and 0.84 and remained the same when the dataset was adjusted to match case numbers or frame samples between hVATS and cVATS.

Conclusions: The comparison of approach-specific accuracy in AI-based surgical workflow recognition suggests that limitations in the field of view associated with different surgical approaches may have influenced model performance. Additionally, validation using a dataset with matched hVATS and cVATS cases suggests that case volume significantly impacts model accuracy. Future studies should explore data augmentation and model adaptation to enhance the generalizability of AI-based workflow recognition across different surgical techniques.

AI Disclaimer: This study utilized Swin Transformer, an AI-based image recognition tool, for automated workflow recognition model development and validation.

P1.07.04 MRD Combined With Radiological Tumor Volume as Tool to Identify Resected NSCLC Patients at High Risk of Recurrence

M. Verzè[1,2], R. Minari[1], P. Bordi[1], G. Bocchialini[3], G. Martines[2], M. Pluchino[1,2], S. D'Agnelli[1,2], L. Gnetti[4], A. Cosenza[1], V. Balestra[3], L. Ampollini[2,3], L. Leo[2], G. Milanese[2,5], C. Roberti[2,5], C. Gallani[2], F. Riva[6], J. Hayes[6], I. Roca Carreras[6], M. Tiseo[1,2]
[1]Medical Oncology Unit, University Hospital of Parma, Parma/IT ,[2]Department of Medicine and Surgery, University of Parma, Parma/IT ,[3]Thoracic Surgery Unit, University Hospital of Parma, Parma/IT ,[4]Pathology Unit, University Hospital of Parma, parma/IT ,[5]Radiological Unit, University Hospital of Parma, Parma/IT ,[6]Guardant Health, Inc., San Francisco/CA/USA

Introduction: Circulating tumor DNA (ctDNA) is a valuable tool for assessing minimal residual disease (MRD) and predicting recurrence in resected non-small cell lung cancer (NSCLC) patients. As MRD assessment in NSCLC remains biologically challenging, combining ctDNA-detection with other biomarkers could increase prognostic value. This study aimed to correlate MRD status with clinical outcome and integrate ctDNA detection with radiological tumor volume to improve risk stratification.

Methods: Patients with a histological diagnosis of stage I-III resectable NSCLC were prospectively enrolled in the RESIDUAL study from December 2019 to July 2022. Plasma samples were collected before surgery (T0), at landmark (T1, 10-days after surgery) and surveillance timepoints (T2, 20 days, T3, 1 months after surgery and every 3 months for the first year and then at the end of the second year after surgery). A plasma sample was further collected if relapse occurred (TRel). All samples were analyzed using Guardant Reveal, tissue-free, methylation-based assay for the detection and quantification of ctDNA (Guardant Health, USA). Receiver operator characteristics was performed by associating the presence of ctDNA at landmark timepoint with the tumor volume. The cut-off for optimal stratification of tumor volume was calculated based on Youden's J and Cox regression analysis was performed.

Results: Forty-eight patients were enrolled with a median age of 72 years (range 47 to 84); 64.6% were males; most patients were stage I (54.2%), followed by stage II (29.2%) and III (16.6%). Thirty-eight patients (79.2%) were adenocarcinoma (ADK), 9 (18.8%) were squamous cell carcinoma (SCC), while 1 (2.0%) had mixed histology ADK-SCC. Five (10%) patients had a systemic adjuvant treatment post-surgery. Median follow-up was 41.8 months (range 1.2 to 59.8) and 19 (39.6%) patients experienced disease recurrence. Two hundred and seventy plasma samples were collected and analyzed. The overall ctDNA detection rate was 16.7% across all timepoints. Pre-surgical ctDNA-detection was higher in both SCC histology and II-III pathological stage patients, and ctDNA-detection tended to have a worse DFS (ctDNA detected yes vs. no: 34.4 vs. 52.1 months; HR 2.13; 95%CI 0.85-5.33, p>0.05). In the landmark analysis, we found that MRD detection after surgery was associated with a significant worst DFS (ctDNA detected yes vs. no: 6.1 vs. 52.1 months; HR 4.91; 95%CI 1.06-22.75, p=0.024). Serial surveillance sampling yielded a median lead time of 5.3 months compared to radiologic recurrence. Lastly, a volume threshold was calculated with T1 ctDNA status and we found that patients with radiological tumor volume higher than 26'378 mL were at higher risk of relapse rather than patients with a lower volume (volume above the threshold yes vs. no: 5.95 vs. NaN; HR 8.48; 95%CI 3.06-23.49, p < 0.0001).

Conclusions: MRD identification in resected NSCLC is associated with a worse outcome and anticipates radiological relapse months in advance. Moreover, the combination of ctDNA and radiological tumor volume allow to develop a combined tool to better identify patients at high risk of recurrence.

P1.07.05 Real-World Biomarker Testing and Treatment Initiation in Patients With Resected Early-Stage NSCLC (eNSCLC) in the US and UK

C. Rinaldi[1], S. Halloran[1], H. Pittell[1], S. Reiss[1], K. Schwed[1,2], E. Fidyk[1], S. Brake[1], E. Castellanos[1,3]
[1]Flatiron Health, New York/NY/USA ,[2]Memorial Sloan Kettering Cancer Center, New York/NY/USA ,[3]Fox Chase Cancer Center, Philadelphia/PA/USA

Introduction: Biomarker testing among patients with eNSCLC is recommended following the approval of immunotherapy and targeted therapies in the neoadjuvant and adjuvant settings. While past studies highlighted the underutilization of biomarker testing in surgically resected eNSCLC, the cause for these gaps remain unclear. This study sought to generate new insights by examining the characteristics associated with biomarker testing in resected eNSCLC, as well as the impact of testing on timeliness of treatment.

Methods: This retrospective study used the electronic health record-derived US and UK Flatiron Health Research Databases and included adult patients with stage IB-IIIA NSCLC who received surgical resection by July 1, 2024. Eligible patients were categorized based on receipt of EGFR/ALK testing in the early setting, with tested patients further stratified by test timing around surgery and neoadjuvant or adjuvant therapy use. Clinical and demographic characteristics were summarized by testing group.

Results: In the US cohort of 13,473 eligible patients, approximately 69% (9,339) received EGFR/ALK testing (Table). More patients in the tested group had Stage IIB or Stage IIIA disease; most characteristics including socioeconomic status were similar across testing groups. Among patients tested, median (IQR) time from initial diagnosis to surgery was 70 (42-127) days for patients tested before surgery versus 22 (1-48) days for patients tested on or after surgery, irrespective of systemic therapy. A higher percentage of patients tested before surgery received neoadjuvant therapy than those tested on or after surgery (30.5% vs 3.6%). Of the 102 eligible patients in the UK cohort, 43 (42%) patients received EGFR/ALK testing, with 15 tested before surgery and 28 tested on or after surgery. Tested patients were more likely to have stage IIB or stage IIIA disease than untested patients (69.8% vs 44.1%). Patients who were tested had a longer time between initial diagnosis and surgery than untested patients (45 vs 33 days).

Conclusions: Despite growing clinical interest, more than 30% of patients with resected eNSCLC did not undergo EGFR/ALK biomarker testing in the US and UK. Testing rates were higher in patients with higher stage of disease, suggesting clinical risk is impacting testing decisions. Biomarker testing in eNSCLC was associated with a modestly longer time to surgery, greatest for testing done before surgery, suggesting planning for biomarker testing is needed to reduce delays in care. Further analyses on the impact of this timing on patient outcomes are needed.

Table. Demographic and Clinical Characteristics of US Patients Stratified by *EGFR/ALK* Early Biomarker Testing

Characteristic	Overall	Has *EGFR/ALK* testing in early setting	No testing in early setting

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.07.06 Impact of Mediastinal Lymph Node Dissection/Sampling on Survival in Frozen Section-Upgraded Invasive Lung Adenocarcinoma

Y.X. Huang, D. Chen, H. Tie
The First Affiliated Hospital of Chongqing Medical University, Chongqing/CN

Introduction: Mediastinal lymph node dissection or sampling (MLND/S) is a vital part of diagnosis and treatment for invasive lung adenocarcinoma. Surgeons frequently rely on frozen section to determine the necessity of MLND/S. Limited studies have evaluated the prognostic significance of MLND/S in patients with invasive adenocarcinoma initially misclassified as adenocarcinoma in situ (AIS) or minimally invasive adenocarcinoma (MIA) by frozen section.

Methods: A retrospective cohort of 635 patients with invasive adenocarcinoma misclassified as AIS/MIA by frozen section was analyzed. These patients with invasive adenocarcinoma include 32 AIS and 603 MIA by frozen section, all of them underwent lobectomy or sublobar resection. Prognostic outcomes, including 5-year overall survival (OS) and recurrence-free survival (RFS), were compared between patients who underwent MLND/S (n=417) and those who did not (n=218). All patients underwent either lobectomy or sublobar resection.

Results: From a preoperative imaging perspective, the chest CT findings of these patients predominantly exhibited imaging characteristics of early-stage lung cancer, with over 80% of nodules measuring less than 3 cm in diameter and more than 50% demonstrating a CTR (consolidation-to-tumor ratio) of less than 0.5. Only one patient died of community-acquired pneumonia in MLND/S group and one patient died of lung cancer metastasis in the non-MLND group. The 5-year OS and RFS rates were 99.7%%/100% in the MLND/S group and 99.5%/99.5% in the non-MLND group, with no statistically significant differences observed (p>0.05). Notably, no positive N1 or N2 lymph nodes were identified in either cohort.

Conclusions: For patients with invasive adenocarcinoma misclassified as AIS/MIA by frozen section, MLND/S does not confer survival benefits, regardless of surgical approach (lobectomy or sublobar resection). These findings suggest that omitting MLND/S in this subset of patients is oncologically safe and may reduce unnecessary surgical trauma.

P1.07.07 The Presence of STAS Leads to Poor Prognosis After Sublobar Resection in Stage I NSCLC: Results From an Individual Patient Data Metanalysis

F.T. Gallina[1], G. Alessandrini[1], D. Forcella[1], R. Tajè[1], L. Mosillo[1], F.L. Cecere[1], F. Cappuzzo[1], E. Mercadante[2]
[1]IRCCS Regina Elena National Cancer Institute, Rome/IT ,[2]Istituto Nazionale Tumori IRCCS Fondazione G. Pascale, Naples/IT

Introduction: Recently, tumour spread through air spaces (STAS) was identified as an independent factor influencing both survival and recurrence rates across various types of lung cancer. To date, the choice of surgical procedure for early-stage NSCLC with STAS remain unclear. This study aimed to analyzed the prognostic impact of STAS on sublobar resections compared to lobectomy for stage I NSCLC.

Methods: An individual patient data (IPD) meta-analysis was conducted, including patients from the studies that analyzed patients with stage I NSCLC treated with sublobar or lobar resections who presented or did not STAS. IPD was reconstructed from Kaplan-Meier curves of the included studies using the IPDfromKM method. The primary outcomes of this study were overall survival (OS) and recurrence free survival (RFS).

Results: The literature search identified 175 records; 6 reports were included in the study. A total of 3063 patients were included, of which, 1471 (48.0%) were treated with lobectomy and 832 (27.2%) presented STAS. Adenocarcinoma was the most common histology (93.7%) while an history of smoking was found in 52% of the included patients. The RFS analysis showed that in the STAS+ group, patients treated with sublobar resections had a significantly shorter RFS compared to lobectomy (HR 1.6 95%CI 1.2-2.1; p= <0.001) while in the STAS- group, patients treated with sublobar resections had a significantly improved RFS compared to lobectomy (HR 0.47 95%CI 0.35-0.67; p= <0.001, Fig. 1a). Data for OS were available for 2748 patients (43.2% lobectomy). In the STAS+ group, patients treated with sublobar resections showed a significantly shorter OS compared to those treated with lobectomy (HR 2.1 95%CI 1.5-2.9; p= <0.001, Fig. 1b). The OS in the STAS- group was significantly improved in the sublobar resections compared to lobectomy (HR 0.4 95%CI 0.29-0.57; p= <0.001).

Conclusions: Our metanalysis showed that patients with stage I NSCLC who presented STAS on pathological examination treated with sublobar resections had a significantly worse RFS and OS compared to lobectomy. Further studies are needed to find predictors of STAS in order to guide the extent of resection.

P1.07.08 Comparing Outcomes of Different Surgical Methods for Small-Sized NSCLC With VPI- A Population-Based Study

X-H. Chiang[1], C-J. Chen[3], C-F. Wei[4,5], C-C. Lin[1], M-W. Lin[1], C-J. Chiang[6,7], W-C. Lee[6,7,8], J-S. Chen[1], P-C. Chen[1,6,9]
[1]National Taiwan University Hospital, Taipei/TW ,[3]National Taiwan University Hospital, Institute of Epidemiology and Preventive Medicine/TW ,[4]National Taiwan University Hospital Yun-Lin Branch, Yun-Lin/TW ,[5]National Taiwan University Hospital, Institute of Environmental and Occupational Health/TW ,[6]National Taiwan University, Taipei/TW ,[7]Taiwan Cancer Registry, Taipei/TW ,[8]Institute of Health Data Analytics and Statistics, Taipei/TW ,[9]National Health Research Institutes, Miaoli/TW

Introduction: Sublobar resection (SR) has been increasingly validated as an effective alternative to traditional lobectomy for small (≤3 cm), peripheral non-small cell lung cancer (NSCLC). However, its efficacy in treating small NSCLC tumors with visceral pleural invasion (VPI) remains uncertain. This nationwide population-based study aims to compare the prognostic outcomes of patients with small (≤3 cm), stage IB NSCLC exhibiting VPI who underwent different extents of pulmonary resection (SR versus lobectomy).

Methods: This study utilized data from the Taiwan Cancer Registry Database (TCRD) from 2011 to 2017. We included patients diagnosed with pathological stage IB non-small cell lung cancer (NSCLC) defined as pT1a-c N0M0 with visceral pleural invasion (VPI) and tumor size ≤ 3 cm. The primary endpoint was overall survival (OS). Propensity score matching (PSM) was employed to balance baseline characteristics between patients undergoing lobectomy versus sublobar resection. Survival outcomes were compared between the matched groups. Subgroup analyses were performed based on the extent of pleural invasion (PL1 and PL2). Cox proportional hazards regression models were used to identify independent predictors of OS in this cohort.

Results: A total of 1330 patients with stage IB NSCLC (≤ 3 cm with VPI) were included, comprising 153 who underwent sublobar resection (SR) and 1177 who underwent lobectomy. The overall cohort had a mean age of 62.6 ± 10.1 years; 60.9% were female, and 75.7% were non-smokers. After propensity score matching (creating 118 matched pairs), Kaplan-Meier analysis revealed no significant difference in overall survival (OS) between the SR and lobectomy groups (log-rank p=0.37). Subgroup analyses confirmed comparable OS between SR and lobectomy, irrespective of PL1 (p=0.55) or PL2 (p=0.46) invasion status. Multivariable Cox regression analysis identified age > 75 years, smoking history, and poor tumor differentiation as independent predictors of worse OS.

Conclusions: In this nationwide study, sublobar resection demonstrated comparable overall survival to lobectomy for patients with small (≤3 cm), stage IB NSCLC exhibiting VPI, including both PL1 and PL2 subgroups. These findings suggest that sublobar resection represents a viable and effective surgical option for carefully selected patients within this specific cohort. Further validation from prospective studies is warranted.

P1.07.09 Real-World Efficacy of an AI-Driven 3D Reconstruction System on Pulmonary Surgery

J. Geng[1,2,3,4,5], H. Zhao[1,2,3,4,5], G. Lin[1,2,3,4,5], X. Chen[1,2,3,4,5]
[1]Peking University People's Hospital, Beijing/CN ,[2]Thoracic Oncology Institute, Peking University People's Hospital, Beijing/CN ,[3]Research Unit of Intelligence Diagnosis and Treatment in Early Non-small Cell Lung Cancer, Chinese Academy of Medical Sciences, Peking University People's Hospital, Beijing/CN ,[4]Institute of Advanced Clinical Medicine, Peking University, Beijing/CN ,[5]Beijing Key Laboratory of Innovative Application of Big Data in Lung Cancer, Peking University People's Hospital, Beijing/CN

Introduction: Three-dimensional (3D) chest CT reconstruction significantly enhances thoracic surgical planning with superior spatial visualization over standard imaging. While our previous multi-reader multi-case study established the benefits of 3D CT, its real-world clinical effectiveness requires further evaluation.

Methods: We retrospectively evaluated an AI-driven 3D reconstruction system implemented in routine practice at our center (July 2022 - Sept 2023). Consecutive patients initially scheduled for lobectomy or segmentectomy were included. Surgeons utilized the AI system based on clinical judgment before surgery. Patients receiving AI-assisted planning (AI group) were compared to those undergoing standard planning (control group) within the same period. We assessed rates of intraoperative procedural modification, standard perioperative outcomes (operative time, blood loss, drainage, length of stay, complications including transfusions, reoperations, chest tube reinsertion), and surgical costs.

Results: This study included 1622 consecutive patients initially scheduled for pulmonary resection, comprising 1038 lobectomies and 584 segmentectomies. The AI-driven 3D reconstruction system was utilized preoperatively at the surgeon's discretion in 17.9% (186/1038) of lobectomy cases and substantially more often, in 58.6% (342/584), of planned segmentectomy cases. For patients initially scheduled for lobectomy, the overall rate of intraoperative conversion to any alternative procedure did not differ significantly between the AI group (3.8%, 7/186) and the control group (3.2%, 27/852; P=0.85). However, the conversion to segmentectomy was significantly more frequent following AI-assisted planning compared to controls (3.8% vs 0.9%; P<0.01). Among patients scheduled for segmentectomy, the use of the AI system resulted in a significant reduction in overall intraoperative procedural modifications (6.1% [21/342] in AI group vs 20.7% [50/242] in control group; P<0.001). This decrease was primarily driven by the complete elimination of conversions to less precise wedge resections in the AI group, compared to a 16.5% conversion rate in the control group (0% vs 16.5%; P<0.001). In cases where the initially planned surgery was performed without modification, most perioperative outcomes showed no significant differences between the two groups. Analysis of costs revealed significantly lower surgical costs for patients in the AI group (RMB: 10505.70[9395.39, 11684.58] vs. 10729.75 [9201.05, 12406.25], P<0.001).

Conclusions: In routine clinical practice, this AI-driven 3D reconstruction system significantly reduced intraoperative procedural modifications during planned segmentectomies, notably eliminating conversions to wedge resection (P<0.001), and was associated with lower overall surgical costs. These findings suggest the system enhances surgical precision and planning, particularly for complex resections, supporting its clinical utility despite minor time implications. Further validation in diverse settings is warranted.

P1.07.10 Prognostic Impact of Resection Margin Distance in Patients With Completely Resected Stage INSCLC After Lobectomy

S. Kim, J.K. Yun, G.D. Lee, S. Choi, H.R. Kim, Y-H. Kim, D.K. Kim, S-I. Park
Asan Medical Center, Seoul/KR

Introduction: Unlike sublobar resection, the prognostic impact of margin distance has not been fully evaluated in patients who underwent lobectomy for stage I non- small cell lung cancer (NSCLC). We investigated the prognostic value of the resection margin distance and determine the cutoff value in these patients.

Methods: Between 2011 and 2021, data of patients with completely resected stage I NSCLC after lobectomy were analyzed. The margin distance and ratio were defined as the distance from the primary tumor to the bronchial resection margin and the margin distance divided tumor size. The optimal cutoff value was selected using a maximally selected log-rank statistic.

Results: A total of 3,727 patients were included as the final cohort, of whom 211 (5.7%), 1202 (32.3%), 1175 (31.5%), and 1139 (30.6%) patients were in stages IA1, IA2, IA3, and IB, respectively. The most optimal cutoffs for the margin distance and the margin ratio for cancer recurrence within 5 years were 25mm and 1.5, respectively. In the multivariable analysis, the margin distance (<25mm vs. ≥25mm; hazard ratio [HR], 1.34; 95% confidence interval [CI], 1.11-1.61; p = 0.002) and the margin ratio (<1.5 vs. ≥1.5; HR, 1.40; 95% CI, 1.14 to 1.71; p <0.001) were significant factors for recurrence-free survival in patients after lobectomy for stage I NSCLC.

Conclusions: The margin distance has a significant prognostic impact in patients who underwent lobectomy for stage I NSCLC. Cutoff values of margin distance ≥25mm and margin ratio ≥1.5 could help clinicians enact proper treatment strategies and surveillance for these patients.

P1.07.11 AI-Based 3D Reconstruction in Lung Surgery

S. Kassahun, W. Schreiner
Goethe University Hospital Frankfurt am Main, Frankfurt am Main/DE

Introduction: Segmentectomy is currently accepted as treatment of choice for <2cm non-small cell lung cancer (NSCLC) leading to comparable disease-free and overall survival as lobectomy, while preserving more lung tissue. However, anatomical variations in vascular and bronchial structures pose challenges. Furthermore, accurately localizing tumors within a lung segment based solely on a CT scan can be challenging. AI-based 3D reconstruction can potentially help recognize these variations and aid in surgical planning, it is not yet routinely implemented.

Methods: We analysed the perioperative data of patients who underwent a lung segmentectomy after 3D lung reconstruction between October 2023 and December 2024 (Group A) and compared them with patients who underwent lung segmentectomy without 3D reconstruction between 2021 and 2023 (Group B). The 3D reconstruction was performed using an AI-based program by "Infervision". Collected data included operative time, blood loss, R0 resection rate, complications (according to Clavien-Dindo classification), hospital stay and conversion rate to open surgery.

Results: Group A included 37 patients with a median age of 67.42 years. Anatomical variations were observed in 26% of arteries and 13% of bronchi. In 17.3% the planned resection was adjusted after 3D reconstruction to achieve the complete resection.

Perioperative data for Group A: median hospital stay of 6 (d), conversion rate of 0%, complication rate of 24.3% (Grade III - 10.8%).

Group B included 46 patients with a median age of 66.00 years. Perioperative data for Group B: median hospital stay of 9 (d), conversion rate of 4.35% and complication rate of 23.9% (Grade III - 15.2%)

Conclusions: 3D reconstruction allows better surgical planning through preoperative identification of anatomical variations and tumor position. It leads to lower complication rates and reduced hospital stay. Further studies are needed to confirm its long-term benefits.

P1.07.12 Independent Risk Factors for Occult Lymph Node Metastasis in cIA Left Upper Lobe Lung Adenocarcinoma: A Nomogram-Based Prediction Model

W. Zhu, D. Luo, F. Xiao, C. Liang
china-japan friendship hospita, Beijing/CN

Introduction: The management of left upper lobe lung adenocarcinoma presents various surgical challenges, particularly in cases of occult lymph node metastasis (OLNM). Inadequate lymph node dissection in patients with clinical stage IA (cIA) disease may compromise oncological outcomes. This study aimed to identify independent risk factors and develop a predictive nomogram for OLNM in cIA left upper lobe lung adenocarcinoma.

Methods: We conducted a retrospective analysis of 452 consecutive patients with clinical stage IA (cIA) left upper lobe lung adenocarcinoma between January 2018 and May 2022.Univariate and multivariate logistic regression analyses were performed to identify preoperative risk factors for OLNM. A nomogram was subsequently developed and validated using receiver operating characteristic (ROC) curve analysis, calibration plots, and decision curve analysis (DCA).

Results: OLNM was identified in 56 cases (12.39%). Multivariate analysis identified four independent predictors: elevated carcinoembryonic antigen (CEA) levels, mean computed tomography (CT) attenuation values, location of tumor, and CT tumor size. The nomogram demonstrated excellent predictive accuracy with an area under the ROC curve of 0.935. Calibration plots showed optimal agreement between predicted and observed outcomes, while DCA confirmed the clinical utility of the model.Three continuous variables were used to predict occult lymph node metastasis, including CEA, CT size and mean CT value. With regard to the cut-off value obtained by the ROC curve, the cut-off value of CEA was 2.45ng/ml (AUC = 0.68). The cut-off value of the CT size was 2.05cm (AUC = 0.72) and the cut-off value of the mean CT value was -19.80 (AUC = 0.87).

Conclusions: This study presents a validated nomogram incorporating CEA levels, mean CT values, location of tumor, and tumor size for predicting OLNM in cIA left upper lobe lung adenocarcinoma. This tool may assist thoracic surgeons in preoperative planning and decision-making regarding the extent of lymph node dissection.

P1.07.13 Impact of TP53 Co-Mutation in Resected Early-Stage EGFR-Mutated Lung Adenocarcinoma

T. Masuda[1], S. Katsumata[1], M. Isaka[1], M. Serizawa[1,2], T. Kawata[1], K. Matsusima[1], K. Hayasaka[1], H. Kojima[1], N. Yokomakura[1], H. Konno[1], T. Nagashima[2,3], K. Urakami[2], K. Yamaguchi[1], Y. Ohde[1]
[1]Shizuoka Cancer Center, Nagaizumi-cho, Shunto-gun/JP ,[2]Shizuoka Cancer Center Research Institute, Nagaizumi-cho, Shunto-gun/JP ,[3]SRL Inc., Tokyo/JP

Introduction: Epidermal growth factor receptor (EGFR) mutations are known as the most common oncogenic driver mutations in lung cancer. With advances in next-generation sequencing techniques, the analysis of co-existing mutations in EGFR-mutated lung adenocarcinoma has progressed significantly. In advanced stage, TP53 co-mutation is associated with poor responses to EGFR tyrosine kinase inhibitors (TKIs). However, the impact of TP53 co-mutations in resected early-stage EGFR-mutated lung adenocarcinoma remains unclear. We aimed to evaluate the impact of TP53 co-mutation on clinicopathological features, prognosis, and recurrence patterns in resected early-stage EGFR-mutated lung adenocarcinoma.

Methods: Four-hundred patients with pathological I-III lung adenocarcinoma who underwent complete resection from January 2014 to September 2018 and examination of genomic alterations using whole-exome sequencing at our institution were screened. Among them, 121 had common EGFR mutations (exon 19 deletions or L858R). We divided these patients into two groups according to co-mutation status of TP53 alteration: TP53 co-mutation group and TP53 wild group. We then compared clinicopathological features, prognostic outcomes, recurrence patterns, and the efficacy of EGFR-TKI treatment post-recurrence between these groups.

Results: TP53 co-mutations were identified in 22 cases (18.2%). The TP53 co-mutation group had significantly more lymphovascular invasion (p = 0.037) and a higher tumor mutation burden (p = 0.007) compared with the TP53 wild group. The TP53 co-mutation group exhibited poorer recurrence-free and overall survival rates [hazard ratio (HR) 2.32, 95% confidence interval (CI) 1.12-4.85, p = 0.025; HR 2.54, 95% CI 1.01-6.36, p = 0.047, respectively] than TP53 wild group. Among the entire cohort of 121 patients, 33 experienced recurrences. Of these, nine patients were in the TP53 co-mutation group, and 24 were TP53 wild group. In the analysis of the initial recurrence sites, there were no significant differences between the two groups. After recurrence, six patients in the TP53 co-mutation group received EGFR-TKIs as first-line treatment (two were treated with first- or second-generation TKIs and four were osimertinib), and 13 patients in the TP53 wild group (eight were first- or second-generation TKIs and five were osimertinib). Progression-free survival in those treated with first-line EGFR-TKIs did not differ significantly between the groups.

Conclusions: The TP53 co-mutation in completely resected early-stage lung adenocarcinoma harboring common EGFR mutation was associated with poor pathological characteristics, and may be associated with poor recurrence-free survival and overall survival. The efficacy of TKI treatment after recurrence needs to be further investigated by collecting more cases.

P1.07.14 Exploring the Effect of Surgical Resection on Quality of Life in Older Adults for Stage IA Non-Small Cell Lung Cancer

J. Zhang[1], L. Gros[2], J. Zhu[1], R. Yip[1], W. Ma[1], D.F. Yankelevitz[1], C.I. Henschke[1]
[1]Mount Sinai Health System, New York/NY/USA ,[2]Centre hospitalier universitaire vaudois, Lausanne/CH

Introduction: With the tremendous strides made in expanding and improving lung cancer screening programs, an increasing number of older individuals are diagnosed with early-stage lung cancer, where surgical resection is curative. Despite this, a balance must be achieved between the need to treat for physicians versus the need to maintain a good quality of life (QoL) for patients, especially for the oldest. We explored the effect of surgical resection on QoL for patients <80 (non-octogenarians) and those ≥80 (octogenarians).

Methods: The study used a prospective cohort of Stage IA non-small cell lung cancer patients enrolled in the Initiative for Early Lung Cancer Research on Treatment (IELCART) study since 2016 who underwent surgery. QoL was measured before surgery, and at 1-, 6- and 12-months post-surgery using SF-12 [physical (PCS) and mental health (MCS)]. Sociodemographic and clinical factors, nodule and surgery characteristics were compared between octogenarians and non-octogenarians. We applied a piecewise linear mixed-effects model to track QoL shifts, with an inflection point at 2 months post-surgery to capture the recovery phase. After adjusting for sociodemographic and clinical variables, including sex, smoking status and pack-years, maximum nodule size on CT, nodule consistency, histology, surgery extent, and type of surgery, the model was used to estimate the baseline, 2-month, and 12-month marginal means of QoL scores.

Results: 818 patients were included, with 104 (12.7%) octogenarians and 714 (87.3%) non-octogenarians. The estimated baseline PCS score was 49.57 for octogenarians and 48.86 for non-octogenarians. At 2 months post-surgery, PCS scores dropped to 46.86 for octogenarians and 44.66 for non-octogenarians. By 12 months post-surgery, both groups showed improvement, with scores of 49.90 for octogenarians and 50.57 for non-octogenarians. The estimated baseline MCS scores were 49.89 for octogenarians and 49.28 for non-octogenarians. At 2 months, scores changed to 47.73 for octogenarians and 49.26 for non-octogenarians, with both improving by 12 months to 50.25 and 50.66, respectively. Pairwise comparisons showed no statistically significant differences between age groups at any time point for either PCS or MCS scores (all p-values >0.90). The comparison did not show any clinically significant (2-3 points) differences between age groups either.

Conclusions: Physical and mental health QoL measures returned to baseline for both non-octogenarians and octogenarians 12 months post-surgery. With the appropriate pre-surgical tests and evaluation, octogenarians can fully be cured of early-stage lung cancer without diminishing their QoL. Longer-term QoL needs to be studied to fully understand the effect of surgery on health outcomes.

Figure 1: Estimated Marginal Means of SF-12 Physical Component Summary (PCS) Scores Comparing Quality of Life in Octogenarians and Non-Octogenarians Undergoing Surgery for Stage IA Lung Cancer at Baseline, 2 Months, and 12 Months Postoperatively

P1.07.15 Oncologic Outcomes of Sublobar Versus Lobar Resection for Clinical Stage IA Pure Solid Non-Small Cell Lung Cancer

D.W. Yoon[1], S. Shin[2], Y.J. Jeon[3], J. Lee[3], S.Y. Park[3], J.H. Cho[3], Y.S. Choi[3], H.K. Kim[3], H.Y. Lee[3]
[1]Chung-ang university hospital, Seoul/KR ,[2]Ewha Womans University, Mok-dong Hospital, Seoul/KR ,[3]Samsung medical center, Seoul/KR

Introduction: The impact of sublobar resection (SL) on the prognosis of small (<3 cm) non-small cell lung cancer (NSCLC) remains uncertain, especially when manifesting as a pure solid nodule on computed tomography. This study aims to evaluate oncologic outcomes in patients with clinical stage IA pure solid NSCLC undergoing SL compared to lobar resection (L).

Methods: Patients with clinical stage IA pure solid NSCLC who underwent curative-intent SL (n=60) or L (n=303) between August 2018 and October 2020 were retrospectively analyzed. After 1:2 propensity score matching based on age, ASA classification, and clinical T category, 60 SL and 120 L patients were included in the final analysis. Recurrence-free survival (RFS), overall survival (OS), and recurrence patterns were analyzed.

Results: After matching, no significant differences were observed between the SL and L groups in terms of age, sex, ASA classification, pulmonary function, clinical T category, peripheral tumor location (outer two-thirds), or pathologic stage. The SL group was associated with significantly fewer dissected lymph nodes than the L group (median, 8 vs. 20; p < 0.01), and pathologic lymph node metastasis (pN+) was less frequent in the SL group (6.7% vs. 13.0%; p = 0.20), although this difference was not statistically significant. Furthermore, significantly fewer patients in the SL group received adjuvant treatment (3.4% vs. 16.0%; p < 0.01). The SL group also showed significantly lower 5-year RFS (58.3% vs. 75.3%; p < 0.01) and OS (75.5% vs. 89.1%; p = 0.01) compared with the L group. Overall recurrence rates were 30.0% in the SL group and 20.8% in the L group (p = 0.20). The incidence of isolated locoregional recurrence (5.0% vs. 0.8%; p = 0.11) and systemic recurrence with concurrent locoregional involvement (8.3% vs. 2.5%; p = 0.12) were higher in the SL group, although the differences were not statistically significant. Systemic recurrence alone was comparable between groups (16.7% vs. 17.5%; p = 1.00).

Conclusions: In real-world practice for patients with clinical stage IA pure-solid NSCLC, the SL group showed significantly worse 5-year survival outcomes compared to the L group. This may be partly explained by the lower number of dissected lymph nodes in the SL group, which could have led to under-staging and, consequently, missed opportunities for appropriate adjuvant therapy. These findings indicate that further research is needed to define appropriate indications for SL in pure-solid NSCLC.

P1.07.16 The Association Between Sarcopenia and Postoperative Outcomes and Survival in Lung Cancer Patients Who Underwent Curative Resections

H. Reddington, I. Emmerick, L. Mcintosh, A. Crawford, K. Do, E. Alkurdi, A. Saremi, C. Ge, M. Maxfield, K. Uy, F. Lou
UMass Chan Medical School, Worcester/MA/USA

Introduction: Sarcopenia, defined as loss of skeletal muscle by the psoas muscle index at the third lumbar (L3) vertebral body, has been associated with post-operative morbidity and mortality. This study evaluated sarcopenia at the fourth thoracic (T4) vertebral body and its association with respiratory postoperative complications (RPOC) and 5-year survival following lung cancer resection (LCR).

Methods: Retrospective cohort study of individuals who underwent LCR from 11/2011-12/2021. Sarcopenia was assessed at L3 using positron emission tomography (PET) scans and at T4 using computerized tomography (CT). Optimal sex-specific T4 cutpoints were identified using Youden's index; traditional L3 cutpoints were employed. Primary outcome was RPOC; secondary outcomes were any postoperative complication (APOC) and 5-year overall survival for Stage 1 LC. Univariate and multivariable logistic regressions were performed using a backward selection method, starting with anatomic resection, age, and waist-hip ratio, and retaining only variables with a p-value of less than 0.05. For survival analysis, Kaplan-Meier curves and Cox regression models were performed.

Results: Among 431 individuals, the prevalence of sarcopenia was 33% by L3 and 64% by T4. On univariate, T4 sarcopenia was significantly associated with an increased odds of RPOC (OR=1.83, 95%CI[1.06-3.13], p=0.027). In multivariable, T4 was associated with RPOC (OR=1.61, 95%CI[1.02-2.98], p = 0.090); DLCO<60 was statistically significant in the final model. DLCO 40to<60 (OR=2.59, 95%CI 1.33-5.07, p = 0.005) and DLCO<40 (OR=2.34, 95%CI[1.33-4.72], p=0.018). L3 was statistically associated with APOC in both univariate analysis and the multivariable final model (OR=1.94, 95%CI[1.24-3.04], p=0.004). Anatomic resections (OR=2.13, 95%CI[1.28-3.54] p=0.004); Age>70 (OR=1.59, 95%CI[1.04-2.43], p=0.033), DLCO<70(OR=1.79, 95%CI[0.37-2.70], p=0.006) increased the likelihood of APOC. Sarcopenia at T4 and DLCO<60 was associated with worse five-year survival.

Conclusions: T4 sarcopenia is associated with increased RPOC and worse five-year survival. Further analysis with larger sample sizes is necessary to evaluate these associations thoroughly.

P1.07.17 A Neglected Dimension in Lung Cancer Surgery: Sleep Disorders Before and After Anatomical Resection

R. Orlandi[1], V. Rossi[1], G. Spreafico[1], E. Funaro[2], E. Privitera[2], G. Putti[2], M. Mantero[2], A. Palleschi[2]
[1]University of Milan, Milan/IT ,[2]Fondazione IRCCS Ca' Granda Ospedale Policlinico Maggiore, Milan/IT

Introduction: Sleep disorders are frequently underdiagnosed in lung cancer patients undergoing surgery, despite their potential detrimental effects on surgical outcomes. Moreover, anxiety and complications are traditionally associated with impaired sleep quality. This study aims to investigate the preoperative prevalence of sleep disturbances in this population, evaluate postoperative sleep changes, and identify contributing factors.

Methods: From January to August 2024, consecutive patients with lung cancer scheduled for upfront minimally-invasive anatomical lung resection at a tertiary university referral center have been prospectively enrolled. Sleep was assessed preoperatively, 45 days and six months after surgery through polysomnography using the Apnoea-Hypopnea-Index (AHI), Epworth-Sleepiness Scale (ESS), International Physical Activity Questionnaire (IPAQ), and Short Form-36 (SF-36) tests. Descriptive statistics were reported as mean±standard deviation or frequency (%). Statistical analysis was performed using SPSS version 23.0, including Chi-square, Mann-Whitney and logistic regression tests.

Results: To date, 32 patients have been enrolled; demographics and baseline pulmonary function results are shown in Table1. 68.8% (22/32) of patients underwent lobectomy, 31.2% (10/32) received segmentectomy; 59.4% of procedures were performed by VATS, 40.6% by RATS. Histologic subtypes included adenocarcinoma (62.5%), squamous cell carcinoma (31.2%), and large cell carcinoma (6.3%). According to 9th TNM edition the tumor was staged I in 65.6%, II in 28.1%, IIIa in 6.3%. The average baseline-AHI was 10.13±9.10 events/h, with an ESS-score of 5.2±3.8. Notably, 46.9% (15/32) of patients had an AHI>5 events/h, suggesting previously undiagnosed sleep apnoea. Hypertension (p-value=0.036), cardiovascular disease (p-value=0.028), and ASA-status (p-value<0.001) were positively associated with preoperative undiagnosed sleep disorders. Early postoperative data revealed that 37.5% (12/32) of patients experienced significant sleep deterioration, persisting at 6 months, while 62.5% (20/32) maintained stable sleep parameters. Sleep deterioration was significantly associated with lobectomy (p-value=0.041), stage II-IIIa disease (p-value=0.045), smoking history (p-value=0.002), hypertension (p-value=0.026) as well as other cardiovascular diseases (p-value=0.039). Interestingly, non-adenocarcinoma histology showed a trend towards increased sleep deterioration, though without reaching statistical significancy (p-value=0.053).

Conclusions: Routine preoperative sleep evaluation can uncover undiagnosed sleep disorders in lung cancer patients, potentially enhancing clinical preparation to surgery. Furthermore, a significant proportion of patients may experience new or worsening postoperative sleep disturbances, possibly related to the extent of resection, disease stage, smoking history, and cardiovascular comorbidities, warranting close perioperative monitoring. Further research is ongoing to assess whether targeted interventions on sleep quality can improve postoperative outcomes. In the era of tailored multimodal strategies, sleep health should no longer be excluded from the multidisciplinary assessment of lung cancer patients.

P1.07.18 Peri-Operative Immune Cell Profiling in Lung Cancer Resection: A Longitudinal Study

L. Staunton[1], D. Doherty[2], G.J. Fitzmaurice[1], R. Ryan[1], K. Gately[2]
[1]St James's Hospital, Dublin/IE ,[2]Trinity Translational Medicine Institute, Dublin/IE

Introduction: Resection surgery for non-small cell lung cancer (NSCLC) is known to trigger systemic inflammation and immunosuppression. CD45RA and CCR7 are markers used to identify naïve, central memory, effector memory and terminal differentiated T cells. Progressive differentiation occurs with down-modulation of CD45RA followed by re-expression in terminal differentiation, alongside the loss of CCR7. This results in T cell senescence, a dysfunctional cellular pathway, acting as T regulatory (Treg) cells and leading to tumour immunity evasion. CD127 is down modulated on Treg cells and signalling through its ligand IL7 is impaired in malignancy. CD25+CD127- markers are used to describe a subtype of Treg cells. Tregs and T cell senescence have been shown to negatively impact overall survival in NSCLC, and a poor prognostic indicator for those undergoing immunotherapy treatment. γδ T cells display potent anti-tumour properties in NSCLC, with trials ongoing for therapeutic use. Vδ1 and Vδ2 are the two main subtypes. We present a longitudinal study examining T cell populations in the peri-operative blood of patients with resectable NSCLC.

Methods: Pre-operative (baseline), and postoperative 2-4 days (1FU) and 6-9 weeks (2FU) post-surgery peripheral blood mononuclear cells (PBMCs) in 18 patients via MultiColour flow cytometry were analysed, using BD LSRFortessa. 56% were female, 67% over 65, 66% adenocarcinoma histology, with Stage 1A to 3A. Median time to follow up is 7 months. FlowJo v10.0 software was utilised to quantify the expression of CD3+, CD4+, CD8+, Vδ1 and Vδ2 T cells, biomarkers CD45RA, CCR7, CD25, CD127 also reviewed. Student's T test and ANOVA were performed on parametric data and Wilson Signed Rank and Friedman's test on non-parametric data via STATABE v18.0 software.

Results: CD45RA positivity, significantly reduced across all timepoints for CD4+ (p= 0.0006) and CD8+ (p= 0.0302) T cells. CD45RA+CCR7+ (naïve T cells) significantly reduced between baseline and 2nd follow up (p=0.0112, p=0.0055). Terminally differentiated T cells (CD45RA+CCR7-) increased across timepoints, however this was not statistically significant (p=0.1787) CD4+CD25+CD127- (denoted CD4+ Treg Cells) significantly increased throughout the three timepoints (p=0.0242). On review of the γδ T cells population, Vδ2 cells increased significantly between baseline and 2nd follow up (p=0.0208). This study shows a reduction of naïve T cells and a move toward terminal differentiation, 6-9 weeks after lung cancer surgery, however this was not statistically significant (p=0.1787). CD4+ Tregs increased significantly (p= 0.0242) between timepoints. These cell populations drive immunosuppression and are poor prognostic indicators for patients undergoing adjuvant treatment. Anti-tumour immune cells, Vδ2, γδ T cells, showed statistically significant increase (p=0.0208) between baseline and 2nd follow up, with 1.65% frequency. Memory and effector T cells as well as correlation with clinicopathological characteristics will be presented. Cohort is currently under expansion to 45 patients, if numbers change to significant when data set increased, this will be presentation.

Conclusions: There is a complex interplay between pro-tumour and anti-tumour immunity post resection for NSCLC. Monitoring for T cell senescence and the increase of Treg cells and γδ T cells can give keen insights into survival as well as prognostic indicators for immunotherapy.

P1.07.19 Prospective Cohort Study on Stage 1A Non-Small Cell Lung Cancer in Older Adults (>80 Years): Prevalence, Surgical Treatment, and Complications

L. Gros[1], W. Ma[2], J. Zhu[2], J. Zhang[2], R. Yip[2], D.F. Yankelevitz[2], C.I. Henschke[2]
[1]CHUV, Lausanne, Switzerland, Lausanne/CH ,[2]Icahn School of Medicine at Mount Sinai, New York/NY/USA

Introduction: With rising life expectancy, more older adults are diagnosed with lung cancer, yet those aged ≥80 years are often excluded from screening programs and trials due to concerns about comorbidities and surgical risks. Data are limited. This study examines the prevalence, clinical presentation, surgery, and postoperative complications in patients aged ≥80 years undergoing surgery for early-stage lung cancer.

Methods: We analyzed data from the Initiative for Early Lung Cancer Research for Treatment (IELCART), a prospective multi-institutional cohort study initiated in 2016. Patients included in this analysis underwent surgical resection for lung cancers measuring ≤30 mm. We compared patients aged ≥80 years to younger ones using descriptive statistics to assess clinical presentation, surgery, and postoperative outcomes.

Results: Among 864 patients who underwent surgery for lung tumors ≤30 mm, 112 (13%) were aged ≥80 years. The median age in this group was 82 years (IQR 81-85) compared to 69 years (IQR 63-74) in patients <80 (p<0.001). Fewer older patients were female (51% vs. 62%, p=0.03). Self-reported race differed significantly between age groups. Patients aged ≥80 were less frequently African American (8.9% vs. 15%) and Asian (6.3% vs. 12%), and more frequently White (79% vs. 60%) or categorized as Other (5.4% vs. 13%) (p=0.001).

Older patients had fewer current smokers (3% vs. 13%) and more former smokers (72% vs. 59%), while never-smoker rates were similar (25% vs. 28%, p=0.002). Comorbidities were generally comparable, including hypertension (57% vs. 51%, p=0.3) and diabetes (15% vs. 20%, p=0.2), but COPD was significantly less common in the older group (9.8% vs. 22%, p=0.002).

Radiologic features were similar between patients aged ≥80 and <80, including nodule consistency (solid: 78% vs. 83%; part-solid: 22% vs. 17%, p=0.3), size (16 mm vs. 15 mm, p=0.3), and location (p>0.9). Older patients underwent fewer lobectomies (21% vs. 33%) and more wedge resections (71% vs. 57%) and segmentectomies (8% vs. 6.9%) (p=0.008). Resected tumors were larger in the older group (18 mm vs. 16 mm, p=0.015). Histology differed (p=0.002), with more adenocarcinomas (88% vs. 75%) and fewer squamous carcinomas (8% vs. 10%) in older patients. Angiolymphatic invasion was more frequent (41% vs. 29%, p=0.008), while vascular invasion (3.6% vs. 3.6%, p > 0.9) and margin status (15 mm vs. 15 mm, p=0.6) were similar.

Postoperative hospital stay was similar (median 3 days, p=0.10), but complications were more frequent in older patients (40% vs. 22%, p<0.001), particularly cardiovascular (11% vs. 5.9%, p = 0.051). Pulmonary (8.9% vs. 5.9%, p=0.2) and infectious (1.8% vs. 0.8%, p=0.3) complications were comparable. ICU admissions (2.7% vs. 0.8%, p=0.1) and 30-day readmissions (7.1% vs. 3.3%, p=0.06) were slightly higher but not statistically significant.

Conclusions: Among 864 patients with resected lung cancer ≤30 mm, 13% were aged ≥80 years. They had similar comorbidities and tumor characteristics but underwent fewer lobectomies and more sublobar resections. In older patients, adenocarcinomas with angiolymphatic invasion were more frequent. Despite more complications, hospital stay and short-term recovery remained comparable to patient<80. Further research is needed to refine screening and treatment for this understudied group.

P1.07.20 Feasibility of Limited Resection in Invasive Mucinous Adenocarcinoma of the Lung

H. Kim, T. Hong, Y. Yang, B. Park, C. Lee, D. Kim, J. Lee
Yonsei University College of Medicine, Seoul/KR

Introduction: Pulmonary Invasive mucinous adenocarcinoma (IMA) is a relatively rare subtype of invasive lung adenocarcinoma. However, the effects of sublobar resection of early-stage IMA remain unclear. This study aimed to evaluate the clinical and oncological outcomes of sublobar resection compared with lobectomy in patients with stage I IMA.

Methods: We retrospectively reviewed patients who underwent surgical resection for stage I lung cancer between 2011 and 2021. Among 2,333 patients, 148 were pathologically diagnosed with IMA. Patients were categorized into two groups based on the surgical procedure: lobectomy and sublobar resection. Clinical characteristics, surgical outcomes, and oncologic outcomes, including overall survival (OS) and relapse-free survival (RFS), were analyzed.

Results: Of the 148 patients with IMA, 118 underwent lobectomy and 30 underwent sublobar resection. During the follow-up period, 11 patients experienced recurrence, 6 in the sublobar group and 5 in the lobectomy group. The sublobar resection group demonstrated significantly worse OS (49.1 vs. 61.0 months, p = 0.009, figure 1) and RFS (45.8 vs. 60.8 months, p = 0.002, figure 2). Notably, all patients in the sublobar group had stage IA disease (100% vs. 74.6% in the lobectomy group, p = 0.005). Other clinical characteristics were comparable between the groups.

Conclusions: Despite being limited to early-stage disease, sublobar resection in IMA was associated with inferior oncologic outcomes compared to lobectomy. These findings suggest that limited resection should be approached with caution in patients with early-stage IMA.

P1.07.21 Lobectomy Versus Multi-Segmentectomy for Left Upper Lobe Lung Cancer: A Propensity Score-Matched Analysis

N. Takeno[1], S. Nomura[2], H. Shiiya[1], R. Nagashima[1], R. Chiba[1], K. Ohtaka[1], A. Fujiwara-Kuroda[1], N. Shiina[2], M. Aragaki[1], M. Kaji[2], T. Kato[1]
[1]Hokkaido University Graduate School of Medicine, Sapporo/JP ,[2]Sapporo Minami-Sanjo Hospital, Sapporo/JP

Introduction: Lobectomy has been the gold standard of surgical treatment for resectable lung cancer. However, recent advancements in imaging and surgical techniques have allowed for the expansion of indications for segmentectomy, particularly for small, peripheral tumors. The left upper lobe is divided into two anatomical units: the upper division (segments 1+2 and segment 3) and lingula (segments 4 and 5), similar to the right upper and middle lobes. Therefore, we hypothesized that multi-segmentectomy, such as trisegmentectomy and lingulectomy, may offer oncologic outcomes comparable to lobectomy for left upper lobe lung cancer. In this study, we compared the oncologic outcomes and survival rates of lobectomy versus multi-segmentectomy in patients with tumors located in the left upper lobe.

Methods: In this retrospective study, we included patients who underwent either lobectomy or multi-segmentectomy resection for left upper lobe lung cancer at two institutions between January 2012 and December 2017. Propensity score matching (PSM) was used to balance baseline characteristics and facilitate fair comparison between the two groups; 5-year overall survival (OS) and 5-year recurrence-free survival (RFS) and patterns of local and distant recurrence were assessed. Additionally, a subgroup analysis was performed for patients with relatively advanced disease, defined as tumor diameter > 2 cm and the consolidation-to-tumor ratio (CTR) > 0.5.

Results: A total of 191 and 57 patients underwent lobectomy and multi-segmentectomy, respectively. Before PSM, there was no significant difference in OS between the two groups. s, although RFS was better in the multi-segmentectomy group. After matching, 53 patients were included in each group, and significant preoperative disparities, such as tumor size and CTR, were effectively neutralized. Post PSM, both OS and RFS remained comparable between the two groups, indicating similar long-term outcomes. Rates of local and distant recurrence were also not significantly different between the two groups. In the subgroup of patients with tumor diameter > 2 cm and CTR > 0.5, no significant differences in OS and RFS were observed.

Conclusions: Our findings suggest that multi-segmentectomy is a lung-sparing alternative to lobectomy for patients with left upper lobe lung cancer, with comparable 5-year OS and RFS. Subgroup analysis comparing the prognosis of relatively advanced cases suggests that multi-segmentectomy for left upper lobe lung cancer may be indicated for more advanced cases. It may also be especially beneficial for patients in whom lung preservation is important due to age or general condition. Further prospective studies are warranted to validate these findings and clarify the patient populations that benefit most from these lung-sparing surgical procedures in left upper lobe lung cancer.

Introduction: Artificial intelligence(AI) may combine omics datasets to create predictive models. LANTERN-project comprises prospective multicenter observational clinical trial involving five European centers. This study aims to develop AI-based predictive model of post-operative complications after lung resection for NSCLC.

Methods: In LANTERN-project Consortium, data from 212 lung cancer patients were retrospectively collected from 5/2023 to 3/2024. Among these, 170 underwent curative surgery for Stage I-III NSCLC and were analyzed, taking into account 59 preoperative clinical features and 52 spirometric variables, to predict post-operative complications. Prediction models were developed on the basis of different feature selection algorithms (MIM, MRMR, Lasso logistic regression) and machine-learning models (logistic regression, elastic-net logistic regression, random forest). Performance was assessed based on 3-fold cross validation using the area under the curve (AUC)metric for clinical parameters only, spirometry parameters only, and their combination. External dataset of 232patients surgical series from a large-volume cancer center was adopted following TRIPOD level2b methodology (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis). The external cohort was homogenous to ours concerning p-stage, kind of surgery and number of complications.

Results: Clinical characteristics are reported in table1. Majority of patients had Stage I disease(135; 79.4%) and underwent lobectomy (98; (57.8%). 29 patients(17.1%) experienced post-operative complications. AI-based models showed Charlson comorbidity index (pathologic score) (AUC=0.70, 95% CI[0.60-0.80])(Figure 1A) and pre-opFEV1 (AUC=0.77, CI[0.65-0.89])(Figure 1B) were the most relevant variables. Combining them, improved overall prediction was obtained (AUC=0.82, CI[0.72-0.92])(Figure 1C).Testing the models on the extern dataset, pathologic score alone was not confirmed to be a predictive factor (AUC=0.49 CI[0.41-0.57]). Pre-opFEV1 (AUC=0.28 CI[0.21-0.34]) and combination of Pathologic score and pre-opFEV1 (AUC=0.68 CI[0.61-0.75]) were confirmed to predict post-op outcome (figure 2). Analysis to predict the cardiovascular complications only (cardiac ischemia, pulmonary embolism, and atrial fibrillation) and the respiratory complications only (pleural effusion, air leakage, subcutaneous emphysema, and pneumonia) was performed. Only pre-opFEV1 was validated (AUC= 0.24 CI[0.13-0.36] and 0.31 CI[0.23-0.39], respectively) for both kind of complications, as well as the combined model (pathological score and pre-opFEV1) (AUC=0.70 CI[0.57-0.83] and 0.66 CI[0.57-0.74]) even though the validation performance was reduced if compared to the FEV1 alone.

Conclusions: Combining collected preoperative data, the identified factors predicted post-operative complications, in particular, FEV1 and (to a lesser extent) the pathologic score. The external validation confirmed that FEV1 only can accurately predict post-operative complications. This parameter could improve the process of counselling and the perioperative management of lung resection candidates.

P1.07.23 Impact of Pulmonary Resection on Early Postoperative Cardiac Function

T. Okazaki, J. Kobayashi, K. Shimada
Osaki Citizen Hospital, Osaki/JP

Introduction: The JCOG0802 trial demonstrated that segmentectomy yielded better prognostic outcomes than lobectomy, previously considered the standard surgical approach. One possible reason for this is the lower incidence of non-lung cancer-related deaths in the segmentectomy group. While comparisons of postoperative cardiac function between pneumonectomy and lobectomy have been reported, similar analyses between lobectomy and segmentectomy remain limited.To evaluate whether there are changes in cardiac function before and after surgery depending on the type of pulmonary resection, focusing on cardiac function as a contributing factor to non-cancer-related mortality.

Methods: We retrospectively analyzed 55 patients who underwent pulmonary resection (segmentectomy or more extensive procedures) for primary lung cancer at our institution between January 2023 and March 2024. All patients underwent echocardiography before surgery and at 1 and 6 months postoperatively. Patients with pre-existing cardiac disease and pre-/post-operative chemotherapy were excluded. Left ventricular function was assessed using plasma brain natriuretic peptide (BNP) levels and echocardiographic left ventricular ejection fraction (EF). Right ventricular function was assessed using tricuspid annular plane systolic excursion (TAPSE), tricuspid annular systolic velocity (S'), and right ventricular fractional area change (RVFAC).

Results: Among the 53 cases, 43 underwent lobectomy (L group) and 10 underwent segmentectomy (S group). The male-to-female ratio was 24:19 in the L group and 7:3 in the S group. The median ages were 73 years (range: 64-82) and 74 years (range: 68-81) for the L and S groups, respectively. Surgical approaches included video-assisted thoracoscopic surgery (VATS), robot-assisted surgery, and thoracotomy, with distributions of 19:21:3 in the L group and 8:2:0 in the S group. Changes in each parameter before and after surgery are shown in Figure 1. No significant differences were observed between the two groups in changes in either left or right ventricular function. Since right middle lobectomy cases (with relatively smaller resected volumes) were included in the L group for right-sided surgeries, a subgroup analysis was conducted limited to patients who underwent left-sided pulmonary resection. These results are shown in Figure 2, which also demonstrated no significant differences between the groups in either left or right heart function.

Conclusions: There was no clear decline in early postoperative cardiac function—including right ventricular function—between lobectomy and segmentectomy. As this study focused only on early postoperative changes, further investigation with a larger cohort and longer-term follow-up is warranted.

P1.07.24 Radicality of Lymphadenectomy in NSCLC Resection: Impact on Survival. Results From the Spanish Video-Assisted Thoracic Surgery Group (GEVATS)

C. Obiols[1], S. Call[1], R. Rami-Porta[1], Á. Jaén[2], D. Gómez de Antonio[3], S. Crowley Carrasco[3], Í. Royo-Crespo[4], R. Embún[4]
[1]Hospital Universitari MútuaTerrassa, Terrassa/ES ,[2]Fundació Docència i Recerca MútuaTerrassa, Terrassa/ES ,[3]Hospital Universitario Puerta de Hierro Majadahonda, Madrid/ES ,[4]IIS Aragón, Hospital Universitario Miguel Servet and Hospital Clínico Universitario Lozano Blesa, Zaragoza/ES

Introduction: The type and the extent of lymph node (LN) dissection in resected non-small cell lung cancer (NSCLC) have been widely evaluated, although the impact on survival remains unclear. While some studies have not observed any difference in survival according to lymphadenectomy practice, others have observed survival benefit according to type of lymphadenectomy, number of resected LN and number of LN stations explored. The objective of this study is to analyse survival differences according to the intraoperative nodal assessment performed (systematic nodal dissection [SND] or no SND) in patients with resected lung cancer from the Spanish Video-Assisted Thoracic Surgery Group (GEVATS).

Methods: Prospective multicentre cohort study of anatomic pulmonary resections (n=3533) performed from December, 2016 to March, 2018. Follow-up was completed in September 2022. For the purpose of this study, SND implied the removal or sampling of a minimum of 6 lymph nodes, at least 3 of them from the mediastinum and always including the subcarinal station. Main surgical, clinical and oncological variables were compared according to the use of SND. Corresponding tests for homogeneity were performed. The Kaplan-Meier method and multivariate Cox regression analysis were used to analyse the overall (OS) and cancer specific survival (CSS) depending on whether SND was performed or not, and then subanalysed by pathologic (p) N category.

Results: After exclusions, 1548 patients were eligible for this study. Kaplan-Meier curves showed no differences in OS (p=0.538) and CSS (p=0.108) in patients undergoing SND or no SND, but there were differences when analysing by pN category (Figure 1A) and also when subanalysing by tumour size (p<0.0001) (Figure 1B). Cox regression analysis revealed no significant difference in lung CSS between SND or no SND in the general cohort (HR 0.98; 95%CI: 0.75-1.28; p=0.883) and in the pN1 cohort (HR 0.68; 95%CI: 0.42-1.11; p=0.123). However, in patients with pN1 and tumour size >3cm, the HR for SND was predictor of better CSS survival (HR 0.49; 95%CI: 0.27-0.88; p=0.017).

Conclusions: SND was not associated with a better overall and cancer specific survival in the GEVATS cohort. However, in the subgroup of patients with pN1 and > 3 cm tumours, the HR for SND group show a significant improvement in survival. Therefore, SND should be performed routinely specially in this subgroup of patients.

P1.07.25 Trajectories of Synchronous Subsolid Nodules in Patients With Resected Subsolid Lung Adenocarcinoma: A Multicenter Cohort Study

S. Jung[1], Y.W. Kim[1,2], S.J. Kim[3], H-R. Kang[4], S. Cho[5], J-H. Chung[1,2], H-S. Lee[3], Y. Ra[3], J.S. Park[1,2], K.W. Lee[1], J.H. Lee[1,2], C-T. Lee[1,2]
[1]Seoul National University Bundang Hospital, Seongnam/KR ,[2]Seoul National University College of Medicine, Seoul/KR ,[3]Hallym University Dongtan Sacred Heart Hospital, Hwaseong/KR ,[4]Veterans Health Service Medical Center, Seoul/KR ,[5]Seoul National University Bundang Hospital, Seongnam/KR

Introduction: Multifocal subsolid nodules (SSNs) are increasingly detected through widespread lung cancer screening and advanced thoracic imaging, representing a spectrum of (pre-)invasive lung adenocarcinomas (LUADs). When synchronous SSNs coexist with surgically confirmed LUAD, their clinical trajectories remain poorly understood, leading to uncertainty in management strategies. Therefore, we aimed to evaluate the trajectories and clinical impact of multi-synchronous SSNs in patients with surgically resected subsolid LUAD and identify features associated with their progression.

Methods: We analyzed the clinical course of synchronous SSNs in individuals who underwent surgical resection for subsolid LUAD between January 2009 and December 2019 at four referral centers in South Korea. Longitudinal outcomes, including growth patterns and subsequent lung cancer diagnosis, were evaluated using comprehensive nodule-level assessments. Multivariable Cox regression models were used to identify risk factors associated with SSN trajectories and patient-level mortality outcomes.

Results: Overall, 409 LUAD patients with 1,791 synchronous SSNs were included, of which 1,002 SSNs were followed up over a mean duration of 80.6 months after the initial surgery. Among the 1,002 SSNs, 16.9% exhibited growth, and 7.9% were subsequently diagnosed as lung cancer—all of which were stage 0-I adenocarcinomas. Factors associated with SSN growth and lung cancer diagnosis included part-solid type, larger nodule size, presence of bubble lucency, and pleural retraction. Notably, the number of synchronous SSNs was not associated with an increased risk of growth. At the individual patient level, neither the absolute number nor the mere growth of synchronous SSNs significantly impacted lung cancer-related mortality or overall survival.

Conclusions: Synchronous SSNs in patients with subsolid LUAD exhibited a considerable growth rate with varying trajectories and clinical impact. Identified risk factors were primarily related to the characteristics of each SSN. Our findings highlight the need for nodule-based, individualized management strategies, along with a more clinically relevant growth threshold to guide balanced intervention decisions.

P1.07.26 Applicability of Artificial Intelligence Based Tumor Segmentation in Planning for Sublobar Resection in Lung Cancer: A Meta-Analysis

P. DAS[1], P. Penumadu[2], P. Subramani[3], S. Gupta[1], S. Bhattacharyya[1], T. Mukherjee[1], A. Choraria[1]
[1]Apollo Multispeciality Hospital, Kolkata/IN ,[2]Sri Venkateswara Institute of Cancer Care and Advanced Research, Tirupati/IN ,[3]Jawaharlal Institute of Postgraduate Medical Education & Research, Pondicherry/IN

Introduction: Patient-specific precise tumor demarcation is critical for successful sublobar resection in lung cancer treatment, particularly for early stage Non Small Cell Lung Carcinomas (NSCLC). Artificial Intelligence (AI) methods, such as deep learning-based segmentation, are emerging as promising tools to assist in tumor delineation for treatment planning. This meta-analysis evaluates the effectiveness of AI-based algorithms in pulmonary nodule segmentation and their possible impact on sublobar resection planning.

Methods: A meta-analysis was performed on studies evaluating AI-based segmentation of pulmonary tumors, using Dice Similarity Coefficients (DSC) as the primary performance metric. PubMed, EMBASE and Google Scholar databases were thoroughly searched for the studies examining performance of various AI-based models in pulmonary tumor segmentation. A total of sixteen studies were included in the analysis and pooled DSC scores were calculated using a random-effects model. Heterogeneity was assessed using the I^2 statistic, and publication bias was evaluated with funnel plots and Egger's test.

Results: The meta-analysis included 16 studies with a total of 17,389 images. The pooled effect size for AI performance in lung nodule segmentation, as measured by the Dice Similarity Coefficient (DSC), was 1.25 (95% CI: 1.00, 1.50). This suggests a strong overall effect of AI in segmenting lung nodules, with consistent performance across studies. High heterogeneity (I^2 = 98%) was observed among the studies. No significant publication bias was detected in Egger's test.

Conclusions: AI-driven segmentation of pulmonary tumours demonstrates high accuracy. The result predicts the promising role of AI in patient-specific surgical planning, particularly in improving precision for tumor localization and resection margin determination in early stage NSCLC. However, further studies are needed to evaluate the direct impact of AI-based localization on surgical precision and postoperative recovery.

P1.07.27 A Newly Developed 3D Simulation System for the Preoperative Planning for Central-Located Lung Cancer

F. Li
Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai/CN

Introduction: Surgical resection of centrally located lung cancer remains challenging due to the tumor's proximity to hilar structures, complicating the identification of optimal resection and anastomosis sites. Conventional CT imaging often fails to provide sufficient spatial detail for precise preoperative planning. This study evaluates the clinical efficacy of Bioxel, a novel 3D simulation system, in improving preoperative planning for centrally located lung cancer surgeries.

Methods: A cohort of 100 patients with centrally located lung cancer underwent chest CT scans. The study comprised two phases. In Part I, Surgeon A (experienced in >300 similar surgeries) utilized Bioxel for preoperative planning in 50 cases, while traditional CT-based planning was employed for another 50 cases. In Part II, Surgeon B performed preoperative planning for 100 patients using CT alone, followed by re-evaluation with Bioxel. Key outcomes included accuracy of tumor invasion assessment, surgical duration, intraoperative blood loss, and positive margin rates.

Results: Bioxel significantly improved the accuracy of tumor invasion assessment from 78% (CT alone) to 89% (Bioxel), with a combined accuracy of 94% when both methods were integrated. Surgical duration decreased from 216.2 ± 1.9 minutes (CT) to 196.8 ± 6.9 minutes (Bioxel; p = 0.008), while intraoperative blood loss was reduced from 301.2 ± 53.7 mL to 158.2 ± 39.8 mL (p = 0.011). Positive surgical margin rates declined from 8% to 2% (p = 0.049).

Conclusions: Bioxel enhances surgical precision and safety for centrally located lung cancer by providing detailed 3D reconstructions and reducing reliance on invasive procedures such as bronchoscopy. These findings underscore its potential to optimize surgical outcomes and streamline clinical workflows.

P1.07.28 Segmentectomy vs Lobectomy for Clinical Stage IA1-2 NSCLC and Upstaging Due to Pathologic Visceral Pleura Infiltration

H. Kaman, T. Stork, O. Özlem, M. Jemsi, A.M. Petrone, Y. Alnajdawi, S. Collaud
Kliniken Der Stadt Köln Merheim, Köln/DE

Introduction: Segmentectomy has become the standard of care in selected patients with stage IA1 and IA2 NSCLC. Lobectomy remains the treatment of choice for stage IB NSCLC. However, it is unclear how patients with clinical stage IA1-2 NSCLC should be managed if upstaging occurs due to visceral pleura infiltration on final pathology (stage IB). We aimed to compare the outcomes of patients who underwent lobectomy or segmentectomy for clinical stages IA1-2 NSCLC and had visceral pleura infiltration on final pathology.

Methods: We retrospectively analyzed all patients with clinical stage IA1-2 NSCLC and postoperative upstaging due to visceral pleura infiltration who underwent surgery at our center between 2013 and 2024. Disease-free (DFS) and overall (OS) survivals were calculated from the date of surgery until recurrence or death, respectively. Univariate analysis was performed to study the impact of clinical variables on DFS and OS.

Results: We identified 46 patients in clinical stage IA1-2 NSCLC who underwent lobectomy (n=18) or segmentectomy (n=28) and had upstaging to stage IB due to visceral pleura infiltration on final pathology report. There was no difference in patient demographics or clinical characteristics between the groups. Most of the resections (89%) were performed by VATS. None of the patients from the segmentectomy group had completion lobectomy due to visceral pleura infiltration on final pathology report. One death occurred within the first 90-days following surgery due to pneumonia in the lobectomy group. Median tumor size was 1.7 cm (range 1-2cm). Number of removed lymph nodes was significantly lower in the segmentectomy group (15.5 vs. 22.5 p=0.031). Resection margin was significantly smaller in the segmentectomy group (median 2.15cm vs. 3.4cm p=0.028). Five-year DFS (62% vs. 83%, p=0.393) and OS (49% vs. 63%, p=0.213) were not statistically significantly between the segmentectomy and lobectomy groups. Patients with a margin to tumor ratio MTR≥ 1 had significantly better DFS (87% vs. 39%, p=0.019) than those with a MTR <1. In patients with less comorbidities (Charlson Deyo comorbidity score < 5), lobectomy offered significantly better survival (100% vs. 44%, p=0.031).

Conclusions: Five-year OS and DFS were not different in our cohort of patients with stage IA1-2 NSCLC who underwent lobectomy or segmentectomy and had upstaging due to visceral pleura infiltration. Therefore, upstaging may not necessitate completion lobectomy. Further studies are still required to confirm our findings.

P1.07.29 Prediction of Postoperative Pulmonary Function and Blood Flow Redistribution Using SPECT/CT in Patients Undergoing Lobectomy

D.G. Cho[1], G. Lim[2], K. Hyun[1], Y.J. Chang[1]
[1]St. Vincent's Hospital, College of Medicine, The Catholic University of Korea, Seoul/KR ,[2]CHA Bundang Medical Center, CHA University School of Medicine, Seongnam/KR

Introduction: Lobectomy remains the standard surgical treatment for patients with non-small cell lung cancer (NSCLC). Accurate preoperative assessment of pulmonary reserve is essential for predicting postoperative outcomes and minimizing complications. Conventional methods for estimating predicted postoperative (ppo) pulmonary function have known limitations. Furthermore, to date, little is known about postoperative pulmonary blood flow redistribution following lobectomy. This study aimed to evaluate the utility of perfusion SPECT/CT in predicting postoperative pulmonary function and to characterize changes in pulmonary perfusion patterns during early period after pulmonary lobectomy.

Methods: A retrospective study was conducted on 63 patients who underwent lobectomy for NSCLC at a single institution between September 2023 and April 2024. Predicted postoperative FEV1 and DLCO values were calculated using the preoperative perfusion fraction from SPECT/CT imaging. These values were then compared with actual postoperative pulmonary function test results to evaluate prediction accuracy. Additionally, for assessing blood flow redistribution, the target lobe's contribution to total perfusion (as measured preoperatively) was subtracted, and the remaining perfusion was assumed to redistribute evenly among residual lobes (expected values). These were compared with actual postoperative perfusion measurements obtained via follow-up SPECT/CT.

Results: The mean predicted postoperative FEV1 using SPECT/CT (ppoFEV1%) was 80.1 ± 6.5%, compared to an actual postoperative FEV1% (apoFEV1%) of 83.7 ± 6.9%. Similarly, the mean predicted postoperative DLCO (ppoDLCO%) was 81.6 ± 8.0%. A weak but statistically significant positive correlation was found between apoFEV1% and ppoFEV1% (r = 0.27, p = 0.03), while a moderate positive correlation was observed between apoDLCO% and ppoDLCO% (r = 0.33, p = 0.007) (Fig.1). Regarding perfusion redistribution, overall right-sided pulmonary flow increased by 2.4% postoperatively. However, subgroup analysis revealed that in right-sided lobectomies, right lung perfusion decreased by 17%, whereas in left-sided lobectomies, right lung perfusion increased by 21.8%, indicating asymmetric compensatory flow.

Conclusions: Perfusion SPECT/CT may serve as a valuable tool for predicting postoperative lung function, particularly DLCO, following lobectomy. Additionally, it provides novel insights into the physiological redistribution of pulmonary blood flow, which appears to vary depending on the laterality of the resected lobe. These findings support the integration of SPECT/CT into preoperative functional assessment to optimize surgical planning and improve patient outcomes.

P1.07.30 Beyond the Lung: Distinct Recurrence Patterns of Mucinous and Non-Mucinous Lung Adenocarcinoma After Surgery

J.O. Lee[1], G.D. Lee[1], S. Choi[1], H.R. Kim[1], Y-H. Kim[1], D.K. Kim[1], S-I. Park[1], J.K. Yun[1], H.K. Park[1]
[1]Asan Medical Center, Seoul/KR

Introduction: Recent findings suggest that invasive mucinous adenocarcinoma (IMA) predominantly exhibits lung-limited behavior, resulting in favorable clinical outcomes following surgical resection. However, comparative research examining recurrence patterns between IMA and invasive non-mucinous adenocarcinoma (INMA) remains scarce due to the rarity of IMA. This study aimed to investigate differences in recurrence patterns between IMA and INMA following surgical resection in lung cancer patients without nodal or systemic metastasis.

Methods: We retrospectively analyzed 4919 patients who underwent curative surgery for adenocarcinoma between 2011 and 2021. Propensity score matching yielded 722 INMA and 368 IMA patients, balancing clinical characteristics. Recurrence patterns were categorized as intrapulmonary (IPR) and extrapulmonary recurrence (EPR). Freedom from recurrence (FFR) and cumulative incidence of recurrence (CIR) analyses were performed to evaluate differences.

Results: A total of 4919 patients were included. After matching, patients with IMA exhibited significantly higher FFR (p=0.03) compared to INMA patients. The overall recurrence rate was lower in the IMA group (8.4% vs. 13.0%, p=0.036). While intrapulmonary recurrence rates were comparable between groups (p=0.54), extrapulmonary recurrence was significantly lower in the IMA group (p=0.017). Multivariate analysis identified IMA histology as an independent factor associated with a lower risk of extrapulmonary recurrence (HR=0.45, 95% CI: 0.22-0.89, p=0.023). Visceral pleural invasion was a significant predictor for extrapulmonary recurrence (HR=3.25, 95% CI: 1.54-6.87, p=0.002).

Conclusions: IMA patients demonstrate better recurrence-free survival and a lower risk of extrapulmonary recurrence compared to INMA following surgical resection. Effective control of intrapulmonary recurrence in IMA patients could potentially enhance long-term survival outcomes.

P1.07.31 Adjuvant Immunotherapy for Clinically Node-Negative Non-Small Cell Lung Cancer

G. Caturegli, M. Canavan, O.F. Ayoade, B.J. Resio, D.J. Boffa
Yale University School of Medicine, New Haven/CT/USA

Introduction: Localized non-small cell lung cancer (NSCLC) is generally treated with upfront surgical resection with curative intent, but many patients harbor clinically occult nodal disease discovered on pathologic evaluation ("nodal upstaging"), a common indication for adjuvant therapy. Here we describe real-world survival trends in the National Cancer Database (NCDB) for localized NSCLC with nodal upstaging who receive different adjuvant modalities, with a focus on immunotherapy.

Methods: Adult patients with clinical T1 or T2, clinical N0, clinical M0, adenocarcinoma or squamous carcinoma of the lung diagnosed between 2017 and 2021 and treated with upfront definitive surgery were included. Patients were grouped based on adjuvant regimen as follows: none/observation, chemotherapy, and chemoimmunotherapy. Kaplan-Meier curves for 3-year overall survival were landmarked at 20 weeks. Propensity-matching for survival curves and Cox proportional hazards models were adjusted for year of diagnosis, age, sex, race, ethnicity, insurance status, facility type, region, Charlson-Deyo score, histologic subtype, clinical and pathologic T and N stages, and R0 resection.

Results: The proportion of nodal upstaging was 11.9%. A total of 6896 patients were eligible for inclusion: 1396 (19.8%) received no adjuvant therapy, 4740 (68.7%) received chemotherapy, and 377 (5.5%) received chemoimmunotherapy. Chemotherapy patients had higher 3-year overall survival (76.8%) than patients receiving chemoimmunotherapy (67.8%) or no adjuvant therapy (62.5%, p<0.0001, Figure 1A). In a Cox model, chemotherapy had lower mortality risk than chemoimmunotherapy (HR 0.56, 95% CI 0.50-0.63, p<0.0001) and observation (HR 0.76, 95% CI 0.61-0.94, p=0.01, Figure 1B). Propensity-matched analysis of 3-year overall survival demonstrated a similar trend: 72.2% chemotherapy vs 67.8% chemoimmunotherapy (p=0.002, Figure 1C).

Conclusions: In this real-world population, adjuvant chemoimmunotherapy did not outperform adjuvant chemotherapy in 3-year overall survival, after propensity matching for patient and tumor characteristics. These results serve as a complement to recently published and ongoing clinical trials of adjuvant chemoimmunotherapeutic approaches for resected NSCLC, suggesting that non-targeted use of adjuvant immunotherapeutic agents may not provide a survival benefit, and highlighting the need for careful patient selection.

Figure 1: A) unadjusted Kaplan-Meier 3-year overall survival curves landmarked at 20 weeks comparing: observation (Obs), adjuvant chemotherapy (C), and adjuvant chemoimmunotherapy (C/IO); B) Cox proportional hazards model directed adjusted curve of 3-group comparison; C) propensity-matched Kaplan-Meier 3-year overall survival curves landmarked at 20 weeks comparing adjuvant chemotherapy (C) and adjuvant chemoimmunotherapy (C/IO).

P1.07.32 Prognostic Value of Consolidation-To-Tumor Ratio in Stage IA Solid Predominant Non-Mucinous Adenocarcinoma

Y. Ahn, J.K. Yun, J. Choe, G.D. Lee, S. Choi, H.R. Kim, Y-H. Kim, D.K. Kim, S-I. Park
Asan Medical Center, Seoul/KR

Introduction: The optimal consolidation-to-tumor ratio (CTR) cutoff for prognostic stratification in radiologically solid-predominant adenocarcinoma (CTR > 0.5) remains unclear. This study aimed to evaluate the prognostic significance of CTR in clinical- stage IA non-mucinous lung adenocarcinoma with CTR > 0.5.

Methods: We retrospectively analyzed patients who underwent curative resection for clinical stage IA non-mucinous adenocarcinoma with CTR > 0.5 between 2011 and 2021. Optimal cutoffs for overall survival (OS) and freedom from recurrence (FFR) were determined using maximized log-rank statistics. Patients were stratified according to the derived CTR cutoff values, and OS and FFR were compared among the CTR groups before and after propensity score matching (PSM).

Results: Among 2,789 patients included, the optimal CTR cutoffs for OS and FFR were 0.84 and 0.85, respectively. Based on the 0.85 cutoff, patients were categorized into three groups: 0.5 < CTR ≤ 0.85 (n = 672), 0.85 < CTR < 1 (n = 229), and CTR = 1 (n = 1,888). OS and FFR were significantly worse in the 0.85 < CTR < 1 group compared to the 0.5 < CTR ≤ 0.85 group ($p < 0.05$) but not significantly different from the CTR = 1 group ($p > 0.05$). These trends persisted after PSM. The 0.85 < CTR < 1 group exhibited a higher proportion of pathological risk factors (high-grade patterns, lymphovascular invasion, and nodal metastasis) than the 0.5 < CTR ≤ 0.85 group (all $p < 0.05$) and was comparable to the CTR = 1 group, except for lymphovascular invasion ($p = 0.045$). Dichotomization into 0.5 < CTR ≤ 0.85 and 0.85 < CTR ≤ 1 revealed significantly worse OS and FFR in the 0.85 < CTR ≤ 1 group across PSM cohorts for both lobectomy and sublobar resection.

Conclusions: A CTR cutoff of 0.85 effectively distinguishes survival outcomes in patients with clinical stage IA adenocarcinoma and CTR > 0.5 and may inform risk stratification and postoperative surveillance.

P1.07.33 Sublobar Resection Versus Lobectomy in Peripheral NSCLC After Neoadjuvant Chemoimmunotherapy: A Retrospective Study

Q. Liang
GuangDong Provincial People's Hospital, Guangzhou/CN

Introduction: The optimal surgical extent (sublobar resection vs. lobectomy) for peripheral non-small cell lung cancer (NSCLC) achieving partial response (PR) or complete response (CR) after neoadjuvant chemoimmunotherapy remains unclear. This study aimed to compare survival outcomes between these approaches.

Methods: Patients with stage IB-IIIA (IASLC 9th edition) peripheral NSCLC who received neoadjuvant chemoimmunotherapy (paclitaxel/nab-paclitaxel/pemetrexed plus carboplatin/cisplatin and nivolumab) at Guangdong Provincial People's Hospital (2018-2024) and underwent surgery after MDT evaluation were retrospectively analyzed. The neoadjuvant treatment lasted for 2-3 cycles depending on the patient's response and tolerance. Imaging-confirmed primary lesions with PR/CR were categorized into lobectomy or sublobar resection groups based on surgical approach. Sublobar resection (including wedge resection and segmentectomy) was selected based on tumor location, size, and patient's cardiopulmonary function. All patients underwent systematic lymphadenectomy (≥ 6 stations). Primary endpoint: DFS; secondary endpoints: OS, recurrence, and complications.

Results: Among 76 patients (sublobar:31; lobectomy:45), baseline characteristics are balanced. At a median follow-up of 28 months, median DFS is unreached in either group (HR=1.25, 95%CI: 0.47-3.30; p = 0.657). Subgroup analyses (Age, Sex, ECOG, PD-L1 expression, Smoking) reveal no DFS differences (p > 0.05). Local recurrence rates (9.68% vs. 8.89%) and distant metastasis rates (12.90% vs. 13.33%) show no significant differences (p > 0.9999).

Conclusions: For peripheral NSCLC patients achieving PR/CR after neoadjuvant chemoimmunotherapy, sublobar resection with lymphadenectomy demonstrated comparable DFS to lobectomy, while preserving more lung function, accelerating postoperative recovery. However, this study is limited by its small sample size and short follow-up duration, necessitating validation through prospective trials with extended follow-up.

P1.07.34 Toxicity Profile for Connective Tissue Disease Patients Treated With Lung Stereotactic Body Radiation Therapy

G. Videtic, A. Ufondu, S. Parker, K. Stephans
Cleveland Clinic, CLEVELAND/OH/USA

Introduction: Connective tissue diseases (CTDs) have historically been considered as presenting contraindications to radiotherapy (RT), in particular lung RT, due to concern for increased rates of severe toxicity. Lung stereotactic body radiation therapy (SBRT) used for inoperable early-stage lung cancer or oligometastases is associated with very low rates of high-grade toxicity. The present study seeks to provide updated information on the toxicity profile of lung SBRT in CTD patients.

Methods: A single institution IRB-approved prospective lung SBRT registry was surveyed for all pts with a connective tissue disease treated for primary cancer, oligometastasis, or salvage from 2006 - 2024. Tumors were characterized as peripheral or central per RTOG criteria. Treatment-related toxicity was graded per CTCAE version 3.0. Medical management of CTDs was recorded at time of cancer consultation.

Results: A total of 118 CTD pts undergoing 144 courses of lung SBRT was available for analysis. Median age was 72 years (65 - 79, IQR) and 82 pts (69%) female. Median KPS was 80 (60 - 90, IQR). Median follow-up was 19 months (9 - 51, IQR). Median tumor size was 1.9 cm (1.5 - 3.2, IQR). Patient characteristics were 55 (47%) with rheumatoid arthritis (RA), 17 (14%) with systemic lupus, 28 (24%) with interstitial/idiopathic lung disease, 6 (5%) with scleroderma, and 42 (36%) with other CTDs. Twenty-six (22%) patients had multiple CTDs. At SBRT, 58 (49%) patients were on active medical treatment. Considering treatment characteristics, median SBRT BED10 was 120 Gy (100 - 149, IQR, with the most common dose schedule being 50Gy/5fx. Twenty-eight tumors (24%) were central, of which 22 (19%) were considered ultracentral.[Overall, 29 (26%) treatments resulted in grade 2 or higher toxicity, with 6 (5%) grade 3 and 1 grade 5 (0.1%). Lung toxicities included 13 (11%) chest wall pain, 11 (9%) pneumonitis, 2 (2%) cough, 1 (1%) pleural effusion, and 1 (1%) hemoptysis. Grade 3 pneumonitis rate was 11% for pts with interstitial/idiopathic lung disease, 2% for RA, and 0% for lupus and scleroderma. The case of grade 5 pneumonitis was associated with interstitial lung disease. No patient with a central tumor had ≥ grade 2 toxicity. Three (14%) of the patients with ultracentral tumors had grade 2 chest wall toxicity, 2 (9%) had grade 2 pneumonitis, 1 (4.5%) had esophagitis and another had hemoptysis. Median time to first pulmonary function test was 2 months (1 - 4, IQR), with a median FEV1% change of -6 (1 - (-35), IQR) and a median DLCO change of -6 (0 - (-30), IQR).

Conclusions: Lung SBRT for CTD patients was not associated with increased rates of high--grade toxicity compared to historical results. Pts with interstitial/idiopathic lung disease were at increased risk for grade 3 or higher pneumonitis.

Introduction: Stereotactic body radiation therapy (SBRT) is the standard of care (SoC) for patients with medically inoperable stage I/II non-small cell lung cancer (NSCLC). However, patients remain at risk for regional and distant recurrence. The PACIFIC-4 trial (NCT03833154) is examining the efficacy and safety of the epidermal growth factor receptor-tyrosine kinase inhibitor (EGFR-TKI) osimertinib following SBRT in a single-arm cohort of patients with medically inoperable stage I/II NSCLC harbouring a sensitising EGFR mutation; the primary endpoint is 4-year progression-free survival (PFS). Here, we report the final results from a global, retrospective, real-world study in patients with medically inoperable stage I/II EGFRm NSCLC who received SBRT as SoC.

Methods: Data were extracted from medical records of adult patients with medically inoperable, stage I/II EGFRm (Ex19del/L858R) NSCLC diagnosed between Jan 2016 and Dec 2019, who received SBRT as SoC. The primary endpoint was real-world PFS (rwPFS). Secondary endpoints included: patient characteristics, mutation testing, treatment patterns, real-world overall survival (rwOS) and real-world time to next treatment or death (rwTTNTD). Data cut-off was 31 Dec 2022.

Results: Eighty-two patients were enrolled across six countries: South Korea (43%), Japan (30%), USA (18%), UK (5%), Austria (2%) and France (1%). Median age was 80 years; 63% of patients were female; 43% were former or current smokers; 44% had Ex19del and 56% had L858R (1% had both mutation types); 72% of patients had an ECOG PS of 0-1. Median follow-up time from the index date was 43.3 months (interquartile range [IQR] 30.8-54.9). Median SBRT dose was 56 Gray (IQR 48-60) in a median (IQR) of 4 (4-4) fractions. Thirty-one patients (38%) progressed following SBRT, of which 25/31 (81%) received a first subsequent treatment: 3 (12%) received SBRT; 21 (84%) received EGFR-TKIs alone (14 gefitinib, 5 osimertinib, 2 afatinib); and 1 (4%) received an EGFR-TKI (gefitinib) + SBRT. Among all 82 patients, the median rwPFS was 47.1 months (95% CI 38.7, 57.8; number of events = 42), rwTTNTD was 49.8 months (40.7, not evaluable [NE]) and rwOS was 62.9 months (50.8, NE); at 4-years, landmark rwPFS rate was 48% (95% CI 35, 60), rwTTNTD rate was 51% (37, 62) and rwOS rate was 68% (55, 78). The factors significantly associated with 4-year rwPFS were older age (≥80 years vs <80 years old) with hazard ratio (HR) of 2.61 (95% CI 1.14, 5.97), p=0.0237, and high Charlson Comorbidity Index score with HR of 1.41 (95% CI: 1.10, 1.81), p=0.0061. In patients who received subsequent treatment following disease progression on SBRT, the median rwPFS2 and rwTTNTD2 were 10.9 months (95% CI 3.1, 14.7) and 12.9 months (95% CI 3.5, 24.6) versus 23.2 months (95% CI 9.7, NE) and 30.0 months (95% CI 11.6, NE) for patients that received first/second-generation EGFR-TKIs (n=17) versus third-generation EGFR-TKIs (n=5), respectively.

Conclusions: In this real-world analysis of patients with medically inoperable, stage I/II EGFRm NSCLC who underwent SBRT as SoC, the 4-year rwPFS rate of 48% suggests an unmet need in this patient population for more effective long-term treatments.

P1.07.36 A Three-Gene Signature Predicting Local Recurrence in Stage I-III NSCLC Patients Treated With Radiation Therapy

V. Lee[1], P. Oh[1], K. Jani[1], A. Rybkin[1], S.Y. Kim[2], A. Patel[2], J.Y.J. Kang[2], H.S. Park[2], T. Hayman[2]
[1]Yale New Haven Hospital, New Haven/CT/USA ,[2]Yale University, New Haven/CT/USA

Introduction: Treatment decisions for non-small cell lung cancer (NSCLC) are largely driven by surgical candidacy and patient preference, with limited molecular biomarkers to guide modality choice. Identifying genomic predictors of recurrence could refine treatment strategies. Prior studies suggest certain mutations influence radiosensitivity, but their clinical significance remains unclear. This study aimed to identify genomic predictors of recurrence in patients treated with radiation therapy (RT) or surgery.

Methods: We analyzed data from the de-identified Flatiron Health-Foundation Medicine NSCLC Clinico-Genomic Database, which includes patients from ~280 US cancer clinics, including clinical stage I-III NSCLC patients treated with RT or surgery. Univariable logistic regression was performed to identify genomic mutations associated with recurrence risk in each cohort. Statistical significance was defined as $p<0.05$. Analyses were conducted using R and Python 3.7 with libraries including scipy.stats, statsmodels, and sklearn. We developed a three-gene signature based on significant univariate Cox results and genes known to influence radiosensitivity, including RB1, BRCA1, and ATM. We conducted a multivariate Cox regression analysis including the three-gene signature and adjusting for birth sex, race, clinical group stage, tumor type, ECOG performance status, and radiation therapy type.

Results: A total of 2,693 patients (mean age 69.9) were analyzed, including 630 who underwent surgery (mean age 69.2) and 2,063 treated with RT (mean age 70.1). Several mutations were associated with decreased recurrence risk in the RT cohort, including ATM (hazard ratio [HR]: 0.66, 95% confidence interval [CI]: 0.50-0.88, p=0.005), BRCA1 (HR: 0.67, 95% CI: 0.46-0.99, p=0.044), and RB1 (HR: 0.68, 95% CI: 0.49-0.94, p=0.019). Presence of a mutation in any of RB1, BRCA1, or ATM was also associated with decreased risk of local recurrence on univariable analysis (HR: 0.63, 95% CI: 0.51-0.78, $p<0.001$) and multivariable analysis (HR: 0.68, 95% CI: 0.54-0.85, p=0.001). Several mutations were associated with increased recurrence risk in the RT cohort including NFE2L2 (HR: 1.94, 95% CI: 1.54-2.45, $p<0.001$), TP53 (HR: 1.49, 95% CI: 1.21-1.83, $p<0.001$), PIK3CA (HR: 1.42, 95% CI: 1.12-1.79, p=0.004), and KEAP1(HR: 1.24, 95% CI: 1.00-1.53, p=0.047). No mutations were significantly associated with decreased recurrence risk in the surgery cohort.

Conclusions: Our findings suggest that ATM, BRCA1, and RB1 mutations are associated with improved outcomes in NSCLC patients treated with RT but not surgery. These associations were not observed in the surgery cohort, highlighting their potential role in RT response rather than general prognosis. In contrast, mutations in NFE2L2, TP53, PIK3CA, and KEAP1 were linked to increased recurrence risk in RT-treated patients, suggesting radioresistance. Clinically, patients with radiosensitizing mutations may benefit from RT and potentially lower radiation doses, while those with radioresistance mutations may require closer surveillance, dose escalation, or consideration of alternative therapy. These findings support the integration of molecular biomarkers into treatment decision-making for early-stage NSCLC. Further studies are needed to validate these results and explore targeted therapeutic approaches.

Introduction: Oncogenic driver testing at diagnosis is critical to identify patients with lung adenocarcinomas most likely to respond to neoadjuvant chemoimmunotherapy (cancers negative for EGFR mutations and ALK fusions) vs. those most likely to respond to targeted therapy (positive for actionable oncogenic drivers).

Methods: The Lung Cancer Mutation Consortium, with the support of the Lung Cancer Research Foundation, designed the LCMC4 LEADER (NCT04712877) neoadjuvant screening trial to determine the frequency of actionable oncogenic drivers (primary objective), using both tissue and blood, from 1000 patients under evaluation for neoadjuvant therapy (operable, resectable, clinical stage IA2-III). Results were provided to treating physicians to assist in planning care.

Results: Twenty-three US sites have enrolled 341 patients to date, with evaluable data in 241 patients with lung adenocarcinomas. In this group, women comprised 57%; former smokers 59%; never smokers 28%; current smokers 14%, with clinical stages as follows: IA2, 23%; IA3, 20%; IB, 11%; IIA/B, 21%; IIIA, 22%; IIIB, 4%. We identified an actionable oncogenic driver using any test performed in a CLIA setting (tissue and/or blood) in 47% of patients (95% CI 41 to 53%). Drivers detected were KRAS G12C in 18% of patients, EGFR exon 19 deletion or L858R in 16%, ALK fusion in 3%, HER2 mutation in 3%, MET exon 14 splice site variants in 2%, EGFR exon 20 insertion in 2%, RET fusion in 2%, ROS1 fusion in 2%, NTRK fusion in 2%, BRAF V600E in 1 %, HER2 amplification in 1%, and 0% MET amplification. Both blood and tissue specimens were evaluated in 114 patients. Among drivers detected in tissue, only 17% were found in paired blood. All 12 drivers found in blood were found in tissue.

Conclusions: We identified an actionable oncogenic driver in half of patients (47% overall, 19% EGFR exon 19 del and L858R or ALK) with lung adenocarcinomas under evaluation for neoadjuvant therapy and surgery. For patients with paired blood and tissue testing, all drivers detected in ctDNA were also found in tissue; across all oncogenic drivers detected in tissue, only 17% tested positive in the paired ctDNA sample. Based on our findings, a positive driver finding in blood-based ctDNA testing is reliable to recommend a targeted therapy. A negative "liquid biopsy," however, is insufficient to support the recommendation of neoadjuvant chemoimmunotherapy and instead should trigger tissue-based testing. Neoadjuvant strategies for lung adenocarcinomas with oncogenic drivers must be individualized, with patients encouraged to enroll in clinical trials. Supported by Foundation Medicine, Inc., AstraZeneca, Genentech, Lilly/Loxo, Merck, BMS/Mirati, Novartis, Pfizer, Regeneron, Sanofi.

Introduction: Previous trials showed perioperative alectinib and lorlatinib were effective for resectable ALK-positive NSCLC. In Stage 1 of the phase II, single-arm, multicenter Neo-INFINITY study, perioperative iruplinalkib demonstrated encouraging efficacy. Here, updated results in ALK-positive cohort were reported.

Methods: This trial was conducted in China, enrolling adults with pathologically confirmed resectable ALK/ROS1-positive NSCLC at stage IB-IIIA or IIIB (T3N2M0 only) according to AJCC Cancer Staging Manual 8th Edition. Treatments consisted of neoadjuvant oral iruplinalkib at 180 mg/day (with a 7-day lead-in at 60 mg/day) for eight weeks, then surgery and adjuvant iruplinalkib at the same dose and lead-in. The total treatment period was no more than two years. The primary outcome was major pathologic response (MPR). The trial adopted Simon's optimal two-stage design, with a threshold of two or more MPR among eight patients in Stage 1 required to proceed to Stage 2, where additional 18 patients would be recruited.

Results: Eleven ALK-positive patients were enrolled from February 2023 to March 2025. Patients had a median age of 60 years (range 42-78), and four (36%) were male. Adenocarcinoma was diagnosed in nine patients (82%), and seven (64%) had IIIA disease. One patient was still on neoadjuvant therapy, and 10 patients completed neoadjuvant therapy and underwent surgery as planned. Five (50%) of 10 achieved MPR, and three (30%) achieved pathologic complete response. Median residual viable tumor percentage reached 18% (range 0-75%). Nine (90%) patients demonstrated an objective response. Four (40%) showed radiologic downstaging, and R0 resection was successful in all cases. Two were waiting for adjuvant therapy initiation. In eight patients on postoperative iruplinalkib treatment, median interval from surgery to adjuvant iruplinalkib initiation and duration of adjuvant iruplinalkib exposure were 29.5 d (range 13-50 d) and 7.0 months (range 1.7-17.5 months), respectively. Two (18%) of 11 patients had grade≥3 iruplinalkib-related adverse events (AE), including alanine aminotransferase increased (two [18%]) and aspartate aminotransferase increased (one [9%]). No serious AE or dose discontinuation was related to iruplinalkib, while three (27%) patients required a dose interruption, and another (9%) had a dose reduction due to iruplinalkib-related AE.

Conclusions: These updated results suggest neoadjuvant iruplinalkib is effective for resectable ALK-positive NSCLC, demonstrating favorable safety profiles. The trial has progressed to Stage 2. Further data will provide insights into long-term outcomes.

Table. Efficacy endpoints

Endpoints	*ALK*-positive patients (n =10)
Major pathologic response	5 (50%)
Pathologic complete response	3 (30%)
Median residual viable tumor percentage	18% (0–75%)
Objective response	9 (90%)
Radiologic downstaging	4 (40%)
R0 resection	10 (100%)

Note: Data are presented as n (%) or median (range).

P1.07.39 Pooled Efficacy and Safety Profile of Neoadjuvant Therapies in Operable EGFR-Mutant Non-Small Cell Lung Cancer: A Meta-Analysis

Y. Wei[1,2,3,4,5], X. Liu[1,2,3,5], X. Li[1,2,3,5], S. Wang[1,2,3,5], K. Chen[1,2,3,5]
[1]Peking University People's Hospital, Beijing/CN ,[2]Thoracic Oncology Institute, Peking University People's Hospital, Beijing, [100044], China, Beijing/CN ,[3]Research Unit of Intelligence Diagnosis and Treatment in Early Non-small Cell Lung Cancer, Chinese Academy of Medical Sciences, [2021]RU[002], Peking University People's Hospital, Beijing, [100044], China, Beijing/CN ,[4]Peking University Health Science Center, Beijing, China, Beijing/CN ,[5]Chinese Academy of Medical Sciences, Beijing/CN

Introduction: The therapeutic efficacy of neoadjuvant therapies for operable EGFR-mutated non-small cell lung cancer (NSCLC) remains debated.

Methods: We searched PubMed, Web of Science, Embase, and conference proceedings through March 20, 2025. Primary outcomes include objective response rate (ORR) and major pathological response (MPR). The protocol is registered with PROSPERO, CRD420251023318.

Results: We included 3 RCTs, 3 RWSs, 13 single-arm trials and 14 retrospective studies involving 1107 patients and four neoadjuvant strategies (chemotherapy [CT], tyrosine-kinase inhibitors [TKI], immune checkpoint inhibitor plus chemotherapy [IO+CT], TKI plus chemotherapy [TKI+CT]). Pooled ORR was significantly higher in TKI (59% [95% CI 0.54-0.64]) and IO+CT (61% [95% CI 0.49-0.72]) compared to CT (37% [95% CI 0.29-0.46]), with TKI+CT demonstrating superior efficacy (70% [95% CI 0.58-0.81]). All regimens achieved near-complete disease control rates (DCR). Pathological outcomes revealed TKI+CT significantly outperformed TKI monotherapy in MPR (25% vs 16%; 95% CIs 0.08-0.46 vs 0.13-0.19), while IO+CT showed marginally higher MPR (29% [95% CI 0.15-0.46]). Similar trends emerged in pathological complete response (PCR) rates. Safety profiles showed comparable adverse event (AE) frequencies between TKI and IO+CT groups. Grade ≥3 AEs occurred in 17% (95% CI 0.09-0.27) of IO+CT and 17% (95% CI 0.06-0.32) of TKI+CT recipients. Mutation subtype analysis revealed differential responses: exon 19 deletions (19del) exhibited superior ORR to TKI vs L858R mutations (65% vs 50%), whereas L858R demonstrated better response to IO+CT across MPR, PCR, and ORR endpoints (ORR: 67% vs 54%). Third-generation TKIs demonstrate superior efficacy compared to overall TKIs (ORR: 67% vs. 59%). Survival analysis limited to TKI monotherapy showed median OS 55.84 months (95% CI 41.16-70.51) and DFS 24.66 months (95% CI 13.48-35.84), with insufficient data for other regimens.

Conclusions: TKI+CT and IO+CT emerge as preferred neoadjuvant strategies, demonstrating complementary efficacy profiles: TKI+CT shows superior radiographic response while IO+CT achieves enhanced pathological regression, aligning with respective mechanisms of tumor growth inhibition versus immune-mediated cytotoxicity. Mutation-specific responses suggest 19del subtypes may derive greater benefit from targeted neoadjuvant therapy, whereas L858R mutations appear more responsive to immunochemotherapy. These findings underscore the potential for precision neoadjuvant approaches based on EGFR mutation subtypes to optimize outcomes in operable NSCLC.

P1.07.40 Detection of ctDNA Prior to Neoadjuvant Osimertinib Treatment Correlates With Decreased EFS in EGFR-Mutated NSCLC

T. Brown[1], M. Gubens[1], C. Mulvey[1], J. Kratz[1], J. Rotow[2], T. Patil[3], J. Riess[4], C. Blakely[1]
[1]University of California, San Francisco, San Francisco/CA/USA ,[2]Dana Farber Cancer Institute, Boston/MA/USA ,[3]University of Colorado Cancer Center, Denver/CO/USA ,[4]University of California, Davis, Sacramento/CA/USA

Introduction: Neoadjuvant osimertinib for the treatment of EGFR-mutated non-small cell lung cancer (NSCLC) is being investigated in multiple clinical trials. In a multi-institution phase II trial of neoadjuvant osimertinib (NCT03433469), 27 patients (pts) with surgically resectable stage I-IIIA (AJCC V7) EGFR-mutant (exon 19 del or L858R) NSCLC were enrolled and achieved a major pathological response (MPR) rate of 15% (J Clin Oncol. 2024 Sep 10;42(26):3105-3114). MPR was not predictive of event free survival (EFS) in this trial. In the metastatic setting, detection of circulating tumor DNA (ctDNA) prior to initiating osimertinib and after initial treatment correlate with worse clinical outcomes. This study investigated whether detection of ctDNA prior to neoadjuvant osimertinib or after 1 cycle of therapy was predictive of EFS in patients enrolled in NCT03433469.

Methods: Plasma was collected prior to initiating neoadjuvant osimertinib (C1D1) and after 1 cycle of osimertinib treatment (C1D28) in patients enrolled in NCT03433469. Plasma samples were analyzed using the Guardant Infinity platform, which detects ctDNA through both genomic alterations and DNA methylation. Kaplan-Meier estimates of median EFS were compared between patients with detectable ctDNA at C1D1 and C1D28 vs. those without detectable ctDNA at these timepoints by the log-rank test. Cox proportional hazards regression was performed to adjust for age, sex, tumor stage, race, EGFR mutation subtype, and time on osimertinib prior to surgery.

Results: 23 of 27 patients had both C1D1 and C1D28 plasma available for analysis. Median follow-up time for EFS was 36.3 months. Patient characteristics are presented in Table 1. 9 of 23 patients (39%) had ctDNA detectable at C1D1. 5 of 23 patients had ctDNA detectable at C1D28. Median EFS was significantly reduced for patients with detectable ctDNA on C1D1 vs. those without (8.5 vs. 45.6 months, HR: 3.78, 95% CI: 1.09 - 13.13, p = 0.036) as well as those with detectable ctDNA on C1D28 vs. those without (18.7 vs. 45.6 months, HR: 5.90, 95% CI 1.09 - 32.01, p = 0.038). Cox regression analysis demonstrated that detectable ctDNA on C1D1 correlated with decreased EFS when controlling for other variables (HR: 10.57, 95% CI 0.98 - 107.6, p = 0.039).

Conclusions: Detection of ctDNA prior to neoadjuvant osimertinib treatment is associated with decreased EFS in patients with EGFR p.L858R or exon 19 deletion mutated NSCLC independent of patient age, mutation subtype, race, or tumor stage. Analysis of ctDNA may be considered prior to initiating neoadjuvant osimertinib therapy.

P1.07.41 Exhaled Breath Analysis in Patients With Resectable NSCLC Treated With Neoadjuvant Immune Checkpoint Inhibitors

K. Cuppens[1], P-J. Volders[1], R. De Vries[2], K. Pat[1], S. Verfaillie[1], B. Maes[1], P. Baas[3]
[1]Jessa Hospital, Hasselt/BE ,[2]Breathomix BV, Leiden/NL ,[3]The Netherlands Cancer Institute, Amsterdam/NL

Introduction: In patients with resectable NSCLC, immune checkpoint inhibition (ICI) became a cornerstone in the curative multimodality treatment. The multicentric, non-comparative phase II study NEOpredict-Lung (NCT04205552) confirmed the primary endpoint of feasibility of neoadjuvant dual PD-1 and LAG-3 inhibition. In this abstract we present data on exhaled breath analysis (EBA).

Methods: Patients with NSCLC (stages IB-IIIA) eligible for surgery were randomized (30 per arm) to receive two preoperative doses (q14d) of nivolumab (240 mg, arm A), or nivolumab plus relatlimab (240/80 mg, arm B or 240/240mg, arm C). Patients treated at the Belgian site could consent to participate in the EBA. The measurement took place at 2 time points: before start of ICI and pre-operatively. Exhaled breath was analyzed real-time using a cloud-based electronic nose: SpiroNose (Breathomix, Leiden, The Netherlands). A model to discriminate healthy individuals from cancer patients was built using linear discriminant analysis (LDA) and validated using leave-one-out cross-validation. A student's T-test identified sensors that differ significantly in patients achieving major pathological response (MPR; <10% residual viable tumor).

Results: In total, 17 patients underwent EBA and 33 measurements were collected. The NEOPREDICT-EBA cohort was compared to a reference healthy (HEALTHref; n=50) and lung cancer (CANref; n=30) cohort. Controls were matched for age, sex, BMI, smoking status, and histology. The NEOPREDICT-EBA cohort was considered a representative cohort: no significant differences were noted with CANref, and a significant distinct breathprint was noted from HEALTHref (Fig.1, LDA AUC=0.969). Of the 17 EBA-patients treated with neoadjuvant ICI, 2 had a major pathological response (MPR). In patients achieving MPR, 2 sensors (S6 and SBH4) differed significantly from patients not achieving MPR (p<0.001) (Fig.2).

Conclusions: Pre-operative exhaled breath analysis can potentially identify patients achieving MPR after neoadjuvant ICI. Further expansion of the data set is planned with neoadjuvant chemotherapy+ICI treated early-stage NSCLC patients.

Figure 1: t-SNE (t-distributed stochastic neighbour embedding) plot comparing healthy controls, lung cancer controls and the NEOPREDICT-exhaled breath analysis cohort.

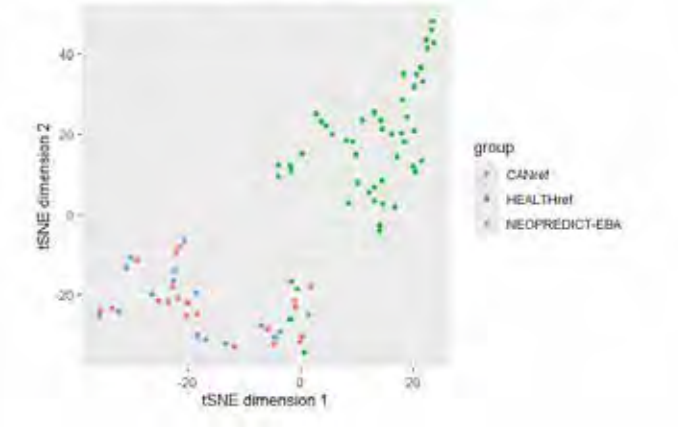

Figure 2: Comparison of patients achieving major pathological response (MPR; <10% residual vital tumor) to non-MPR patients. A statistically significant difference was noted in sensors S6 and SB4H (both p <0.001).

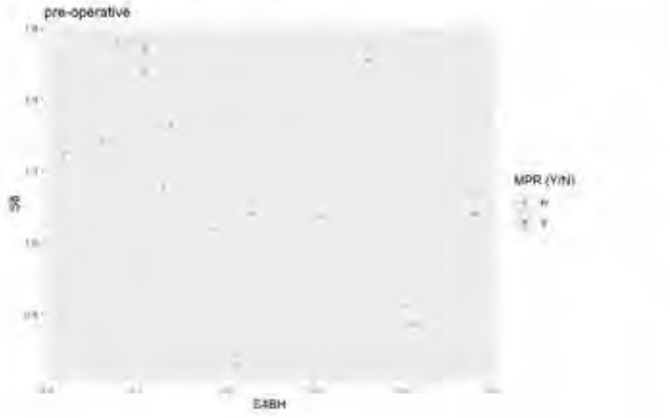

Keywords: neoadjuvant, immune checkpoint inhibitor, exhaled breath analysis

P1.07.42 Multi-Temporal Imaging and CT-To PET Translation Based Predictive Model on Neoadjuvant Immunotherapy for Non-Small Cell Lung Cancer Patients

H. Zhou, M. Li, M. Weng, Z. Huang, L. Yao, S. Wu, G. Liao, C. Cai, R. Liu, Y. Lu
Department of Thoracic Surgery, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN

Introduction: The efficacy of neoadjuvant immunotherapy (NIT) for non-small cell lung cancer (NSCLC) is challenged by the spatiotemporal heterogeneity (TSH) of tumors, complicating reliable patient selection. Radiomics-based biomarker prediction models, including those leveraging PET and CT radiomics, hold promise in addressing this challenge. Delta radiomics, which captures dynamic changes in imaging features over time, offers a more nuanced representation of TSH. This study aims to develop a multimodal predictive model incorporating delta radiomics to assess the efficacy of NIT in NSCLC patients.

Methods: We retrospectively analyzed 149 NSCLC patients (stage IA-IIIB) from Guangdong Provincial People's Hospital who underwent pre-NIT and pre-surgical chest CT and PET/CT scans with pathological confirmation. The dataset was divided into training and validation cohorts in a 7:3 ratio. Our previous work introduced a generative adversarial network (GAN)-based image-to-image translation model capable of CT-to-PET translation (CPT), facilitating the generation of metabolic features. We leveraged this model to extract multi-timepoint delta radiomics features and integrated CT, PET, and metabolic data into a multimodal collaborative learning framework to predict NIT response.

Results: In preliminary analyses, we evaluated the performance and stability of nine predictive models, identifying XGBoost as the most stable and effective. Among single-modality delta radiomics features, ΔCT exhibited the highest predictive performance (AUC: 0.804, 95% CI: 0.730-0.869), outperforming both ΔPET (AUC: 0.723, 95% CI: 0.637-0.797) and ΔMeta (metabolic) features (AUC: 0.731, 95% CI: 0.644-0.810). When combining baseline and delta features, the integration of baseline metabolic and ΔMeta features yielded an AUC of 0.796 (95% CI: 0.720-0.862), comparable to baseline CT and ΔCT features (AUC: 0.783, 95% CI: 0.704-0.859) and superior to baseline PET and ΔPET features (AUC: 0.752, 95% CI: 0.671-0.827). The highest predictive performance was achieved by integrating ΔCT and ΔPET (AUC: 0.855, 95% CI: 0.791-0.913), surpassing the model incorporating ΔCT, ΔPET, and ΔMeta features (AUC: 0.788, 95% CI: 0.708-0.861).

Conclusions: Our delta-radiomics-based multimodal model offers a cost-effective, non-invasive, and reproducible strategy for predicting NIT efficacy in NSCLC, enabling more precise patient stratification and treatment optimization.

Chan School of Public Health, Harvard University, Boston/MA/USA ,[8]Massachusetts General Hospital, Boston/MA/USA

Introduction: While neoadjuvant chemotherapy combined with PD-(L)1 blockade improves clinical outcomes in patients with early-stage non-small cell lung cancer (NSCLC), most patients do not achieve a pathologic complete response (pCR) and develop disease recurrence. This study aims to identify clinically available biomarkers of response or resistance to neoadjuvant chemoimmunotherapy (CT-ICI).

Methods: This multicenter, retrospective study analyzed clinicopathologic and genomic data from patients with stage IB-IIIC NSCLC treated with neoadjuvant CT-ICI, ± adjuvant immunotherapy, across six academic centers in the US and EU. Tumor mutational burden (TMB), assessed using OncoPanel and MSK-IMPACT platforms, was normalized using the ordered quantile normalization transformation.

Results: A total of 221 patients who received neoadjuvant CT-ICI were included. Median age was 67 years, 50.7% were female, and 90.5% had a history of smoking with a median tobacco exposure of 30 pack-years. Most patients had stage IIB-IIIA disease (78.3%). Patients who achieved a pCR (N=58), had significantly longer median event-free survival compared to those without pCR (not reached vs. 20.5 months, p=0.001). There was no difference in pCR rates between patients with non-squamous (N=151) vs. squamous (N=70) histology (odds ratio [OR] 1.2, p=0.62). Baseline PD-L1 tumor proportion score (TPS) ≥50% (N=69) was associated with the highest pCR rate, compared with 1-49% (OR 2.9, p=0.004) and <1% (OR 5.2, p<0.001). Paired PD-L1 TPS pre- and post-CT-ICI was available for 27 cases and, among them, PD-L1 expression increased in 40.7% and decreased in 37.0%. Higher TMB (≥90th percentile) was associated with greater likelihood of pCR (OR 4.42, p=0.008). Concurrent PD-L1 and TMB were available in 93 patients. The highest pCR rate was observed in the High-TMB/PD-L1-positive group (46.2%, N=6/13), and the lowest in the Low-TMB/PD-L1-negative group (6.1%, N=2/33) (Figure 1A). Genomic data were available for 98 patients who had targeted exome sequencing. pCR was lowest in patients with co-occurring KRAS/STK11 (0%, N=0/7) and KRAS/KEAP1 (12.5%, N=1/8) mutations (Figure 1B-C). Among 127 patients with TP53 mutational status available, the KRAS/TP53 co-mutant subgroup had the highest pCR rate (50%, N=7/14) (Figure 1D).

Conclusions: Patients with high PD-L1, elevated TMB, or KRAS/TP53 co-mutations were more likely to achieve a pCR after to neoadjuvant CT-ICI, while those with KRAS/STK11 or KRAS/KEAP1 mutations showed limited benefit. These findings support the integration of molecular and immunologic biomarkers into treatment algorithms to optimize patient selection and enhance therapeutic efficacy, underscoring also the need for novel strategies to overcome resistance in biomarker-defined subgroups.

P1.07.44 Multicenter Assessment of Clinical-Radiomic Predictors for Pathologic Response in NSCLC Patients Receiving Neoadjuvant Chemoimmunotherapy

M. Zhang
Tianjin Medical University Cancer Institute and Hospital, Tianjin/CN

Introduction: This study aimed to identify clinical factors and develop a predictive model for pathologic complete response (pCR) and major pathologic response (MPR) in non-small cell lung cancer (NSCLC) patients receiving neoadjuvant chemotherapy combined with immune checkpoint inhibitors (ICIs).

Methods: Cases meeting inclusion criteria were divided into high- and low-risk groups according to 75 clinical indicators based on 10-fold LASSO selection. Logistic regression was employed to analyze both pCR and MPR. The accuracy of the nomograms was assessed using the time-dependent area under the curve (AUC).

Results: A total of 883 patients from four multiple centers were included in the study, with 526 assigned to the training set and 357 to the testing set. The AUC was determined for the prediction of pCR (training: 0.92; testing: 0.87) and MPR (training: 0.94; testing: 0.85). Significant associations were observed between the preoperative tumor maximum diameter, preoperative tumor maximum standardized uptake value (SUVmax), changes in tumor SUVmax, percentage of tumor reduction, baseline total CYFRA21-1 and pathological response ($P < 0.001$).

Conclusions: The combined application of clinical indicators including non-invasive tumor imaging and hematology can help clinicians to obtain a higher ability to predict NSCLC patient's pathological remission, and the effect is better than that of clinical factors alone. These findings could help guide personalized treatment strategies in this patient population.

Lee Moffitt Cancer Center and Research Institute, Tampa/FL/USA ,[5]St. Francis Medical Center, Jackson St Monroe/LA/USA ,[6]University of Miami Sylvester Comprehensive Cancer Center, Miami/FL/USA ,[7]Dana-Farber Cancer Institute, Dana-Farber Cancer Institute, Boston/MA/USA

Introduction: Neoadjuvant chemo-immunotherapy has emerged as a transformative approach for early-stage NSCLC, offering survival and surgical benefits over traditional adjuvant strategies. This study evaluates the comparative impact of neoadjuvant versus adjuvant immunotherapy on long-term survival in operable NSCLC using real-world data from the TriNetX database

Methods: We conducted a retrospective cohort study of patients with operable NSCLC treated with neoadjuvant chemo-immunotherapy or adjuvant immunotherapy. Propensity score matching addressed baseline differences, ensuring comparability across groups. Key characteristics before matching included significant imbalances in male sex (42.5% vs. 48.7%, p=0.006), White race (55.8% vs. 61.1%, p=0.019), history of cerebrovascular disease (26.4% vs. 20.9%, p=0.004), and liver disease such as cirrhosis (35.2% vs. 25.1%, p<0.001). Matching yielded balanced cohorts (all p>0.05) for analysis. Key outcomes included 5-year and 10-year mortality rates. Absolute risk reduction (ARR), number needed to treat (NNT), and adjusted odds ratios (aOR) were calculated.

Results: In the cohort study, Neoadjuvant chemo-immunotherapy demonstrated significant survival benefits compared to adjuvant immunotherapy in operable NSCLC. Significant survival benefits were observed in females (RR: 0.53, 95% CI: 0.31-0.90, p = 0.0167) and White patients treated with neoadjuvant therapy compared to adjuvant treatment (RR: 0.56, 95% CI: 0.39-0.77, p = 0.0004) Hispanic patients showed no differences in outcomes between the two approaches. Notably, no significant differences in the frequency of immunotherapy-related adverse events were documented in any specific subgroup. Furthermore, one additional life was saved for every 17 patients treated with neoadjuvant chemo-immunotherapy over 5- and 10-year periods. Adjusted analyses revealed substantial mortality reductions (5-year aOR: 0.59, 95% CI: 0.42-0.83; 10-year aOR: 0.59, 95% CI: 0.42-0.83), providing a strong reassurance of its effectiveness and clinical utility.Conclusion: Our study underscores the transformative benefits of neoadjuvant chemo-immunotherapy in early-stage NSCLC, with significant reductions in 5- and 10-year mortality rates and significant advantages in key subgroups. However, women and racial minorities were underrepresented in the cohort, limiting the generalizability of our findings. Neoadjuvant chemo-immunotherapy offers a compelling strategy for improving outcomes in operable NSCLC with survival benefits compared to an adjuvant therapy approach.

Conclusions: Our study underscores the transformative benefits of neoadjuvant chemo-immunotherapy in early-stage NSCLC, with significant reductions in 5- and 10-year mortality rates and significant advantages in key subgroups. However, women and racial minorities were underrepresented in the cohort, limiting the generalizability of our findings. Neoadjuvant chemo-immunotherapy offers a compelling strategy for improving outcomes in operable NSCLC with survival benefits compared to an adjuvant therapy approach.

Outcome	Chemo-Immunotherapy Neoadjuvant Immunotherapy (%)	Adjuvant Immunotherapy (%)	Absolute Risk Reduction (ARR)	Number Needed to Treat (NNT)
5-Year Mortality	9.8	15.6	5.8%	17
10-Year Mortality	10	16	6.0%	17

P1.07.46 Adjuvant Systemic Therapy for Resected Stage IB-IIA NSCLC (AJCC 8Th Edition): A Real-World Cohort Study From SEER Database

Z. Sun, C. Zhao, X. Li
Peking University People's Hospital, Beijing/CN

Introduction: Although adjuvant chemotherapy is recommended for complete resected stage IB-IIA NSCLC with high-risk features, the role of adjuvant therapy in this particular population remains controversial.

Methods: Surgical resected NSCLC patients diagnosed as pathological stage IB-IIA according to AJCC 8th edition staging system were identified in SEER database (2007-2021). Survival outcomes were compared between adjuvant and observation groups. Multivariate Cox and competing risk regression models were built to identify prognostic factors and adjust for covariates in subgroup analyses.

Results: A total of 25919 surgical resected stage IB-IIA NSCLC were enrolled in the study, among which only 3497 (13.5%) received postoperative adjuvant treatment in the real world. The adjuvant therapy rates for stage IB, IIA, and stage IB-IIA patients with high-risk features were 10.9%, 25.0%, and 14.6%, respectively. In the entire cohort, although adjuvant therapy was an independent favorable prognostic factor for overall survival (OS) (HR 0.89, 95%CI 0.84-0.95, P < 0.001), it was not associated with improved lung cancer-specific survival (LCSS) (SHR 1.04, 95%CI 0.97-1.12, P = 0.290). Subgroup analyses revealed that adjuvant therapy was not a favorable prognostic factor for stage IB patients, regardless of the presence or absence of high-risk features; however, it was significantly associated with improved OS (HR 0.75, 95%CI 0.67-0.83, P < 0.001) and LCSS (SHR 0.87, 95%CI 0.76-0.99, P = 0.044) in stage IIA patients. Notably, the survival benefits derived from adjuvant systemic therapy was more prominent in stage IIA NSCLC with high-risk features (OS: HR 0.69, 95%CI 0.60-0.79, P < 0.001; LCSS: SHR 0.76, 95%CI 0.64-0.90, P = 0.001).

Conclusions: Adjuvant therapy was significantly associated with improved OS and LCSS in surgical resected stage IIA NSCLC, especially for those with high-risk features; however, it was not a favorable prognostic factor for stage IB patients, regardless of the presence or absence of high-risk features.

Introduction: Osimertinib - a third-generation, central nervous system-active epidermal growth factor receptor (EGFR)-tyrosine kinase inhibitor (TKI) - is recommended as adjuvant treatment for resected stage IB-IIIA EGFR-mutated non-small cell lung cancer (NSCLC), based on significant improvements in disease-free survival (DFS) and overall survival (OS) with 3 years adjuvant osimertinib versus placebo in the phase III ADAURA trial (NCT02511106). Early treatment discontinuation in the adjuvant setting may impact patient outcomes. We performed an exploratory analysis of ADAURA to further examine reasons for early treatment discontinuation.

Methods: Patients with completely resected EGFR-mutated (Ex19del/L858R) stage IB, II or IIIA NSCLC (AJCC 7th edition) were randomised 1:1 to osimertinib 80 mg once daily (n=339) or placebo (n=343) until disease recurrence, treatment completion (3 years), or another discontinuation criterion was met. Patients with early discontinuation of osimertinib (defined as treatment for <34 months) were analysed to assess baseline characteristics, disease recurrence and reasons for discontinuation (including adverse events [AEs]). Data cut-off: 11 Apr 2022.

Results: Overall, 110 patients in the osimertinib arm discontinued treatment early; reasons for discontinuation included: AE (36%), patient decision (31%), disease recurrence (27%) and other reasons (5%). Baseline characteristics of patients with early discontinuation were consistent with the overall population (median age 66 years; 64% female; 38%/31%/31% stage IB/II/IIIA disease). Amongst patients with early discontinuation, 42 (38%) had an AE leading to treatment discontinuation. AEs leading to discontinuation varied, with most Medical Dictionary for Regulatory Activities (MedDRA) preferred terms occurring in ≤2 patients; those reported in >2 patients were all known adverse drug reactions (ADRs) for osimertinib/TKIs and included interstitial lung disease (n=8; five Grade 1 events and three Grade 2 events), electrocardiogram QT prolonged (n=4; three Grade 2 events and one Grade 3 event), pruritus (n=3; one Grade 1 event, two Grade 2 events), decreased appetite (n=3; one Grade 2 event and two Grade 3 events) and diarrhoea (n=3; two Grade 2 events and one Grade 3 event).

Conclusions: Early treatment discontinuation remains a significant issue in the adjuvant setting, often driven by known ADRs, patient withdrawal or disease recurrence. These data highlight the need for proactive AE management to address these challenges. Healthcare providers should ensure thorough communication with patients about the risks and benefits of continuing versus discontinuing treatment, aiming to enhance adherence and optimise patient outcomes.

P1.07.48 Furmonertinib as Adjuvant Therapy in Postoperative EGFR-Mutated Stage IB-IIA NSCLC With High-Risk Pathological Factors

X-L. Li, J. Fan
Shanghai General Hospital, Shanghai/CN

Introduction: Non-small cell lung cancer (NSCLC) patients with high-risk pathological factors such as micropapillary (MP), solid (S), and spread through air spaces (STAS) have shown poor prognosis in previous studies. Furmonertinib (AST2818) is a novel, promising oral third-generation epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI), which has demonstrated efficacy in tumors harboring sensitive EGFR mutations and T790M resistance mutation. Here, we investigated the efficacy and safety of furmonertinib as adjuvant therapy in postoperative EGFR-mutated NSCLC patients with high-risk pathological factors.

Methods: Patients who underwent radical lung cancer surgery with both EGFR mutations and MP/S/STAS were enrolled and received furmonertinib 80mg daily. The disease-free survival (DFS), safety and tolerability were evaluated. NCT05165355.

Results: This study has prospectively enrolled 79 patients who were pathologically confirmed adenocarcinoma, EGFR mutation positive (exon 19 deletion/L858R), stage IB-IIA NSCLC. All of them had at least one high-risk pathological factor. There were 56 patients with MP, 14 with S, and 53 with STAS. By the cut-off date of March 28, 2025, all patients were alive and with no radiographic recurrence. The median follow-up time was 24.6 months. During therapy, 17 (21.5%) patients had treatment-related adverse events (TRAEs) of any grade. The most common TRAEs were rash (15, 19.0%), diarrhea (4, 5.1%) and mouth ulcer (1, 1.2%). Only 1 (1.2%) patient had TRAEs of grade 3 or higher.

Conclusions: This is the first prospective study to demonstrate that furmonertinib has good efficacy and a tolerable safety profile as adjuvant therapy in EGFR-mutated early NSCLC patients with high-risk pathological factors who underwent radical lung cancer surgery.

Introduction: In 2024, alectinib was approved as adjuvant treatment for patients with non-small cell lung cancer (NSCLC) after resection who harboring a rearrangement in the anaplastic lymphoma kinase (ALK) gene (ALK-positive) based on the results of the ALINA trial in Japan. However, the effect of cytotoxic adjuvant chemotherapy (ACT) has not been fully explored in ALK-positive NSCLC. The aim of this study was to evaluate the role of cytotoxic ACT based on ALK status in patients with stage II-III lung adenocarcinoma (jRCT1050240057).

Methods: We conducted a multicenter retrospective study for patients with lung adenocarcinoma who underwent radical resection between 2011 and 2018 at 27 centers in Japan. Of 1028 patients with pathologic stage II-III (8th edition) lung adenocarcinoma without epidermal growth factor receptor mutation, all of them were tested for ALK status. Among them, 793 patients who underwent anatomical resection with mediastinal lymph node dissection were included in this study. We estimated inverse probability weighting (IPTW) to adjust for confounding variables, including age, sex, smoking status, performance status, and pathological stage associated with the administration of cytotoxic ACT. We evaluated recurrence-free survival (RFS) and overall survival (OS). The median follow-up was 51 months (IQR 31-65 months).

Results: Of 793 patients, ALK-positive adenocarcinoma was detected in 58 patients (7%): 37 (64%) received cytotoxic ACT (ACT group), while 21 (36%) did not (non-ACT group). There were no considerable differences for RFS between those who received cytotoxic ACT and those who did not [5-year RFS: 27% vs. 35%, HR = 0.86 (0.42-1.76)]. However, OS was substantially better in those who received ACT than in those who did not [5-year OS: 90% vs. 69%, HR = 0.19 (0.04-0.81)]. In 80 weighted patient cases (ACT group, 37; non-ACT group, 43), there were no considerable differences for RFS and OS between those who received cytotoxic ACT and those who did not [5-year RFS: 27% vs. 88%, HR = not estimable, and 5-year OS: 90% vs. 100%, HR = not estimable]. Of 735 patients with ALK-negative adenocarcinoma, 414 (56%) received cytotoxic ACT, while 321 (44%) did not. Both RFS and OS were substantially better in those who received cytotoxic ACT compared to those who did not [5-year RFS: 43% vs. 33%, HR = 0.67 (0.56-0.81), and 5-year OS: 72% vs. 57%, HR = 0.55 (0.43-0.71)]. In 828 weighted patient cases (ACT group, 414; non-ACT group, 414), both RFS and OS were substantially better in those who underwent cytotoxic ACT than in those who did not [5-year RFS: 43% vs. 36%, HR = 0.72 (0.60-0.86), and 5-year OS: 72% vs. 60%, HR = 0.61 (0.48-0.77)].

Conclusions: Although this study has limitations due to its retrospective design, the effect of cytotoxic ACT for stage II-III lung adenocarcinoma varied by ALK status. Our study demonstrated that the efficacy of cytotoxic ACT may be limited in patients with ALK-positive adenocarcinoma.

P1.07.50 Aumolertinib as Adjuvant Therapy in EGFRm Stage I-III NSCLC With High-Grade Histological Patterns: 3-Year Dfs Rate Updated

S. Wu[1], X. Chen[1], H. Shen[2], J. He[1], Y. Xi[1], L. Wang[1], B. Chen[1], C. Lin[1], H. Yu[1], X. He[1], J. Gao[1], Y. Xiang[1], S. Tong[1], W. Shen[1]
[1]The Affliated LiHuiLiHospital of Ningbo University, Ningbo/CN ,[2]The Second Hospital of Ningbo, Ningbo, China, Ningbo/CN

Introduction: EGFR-mutated (EGFRm) lung adenocarcinoma patients with high-grade histological patterns are known to be associated with poor prognosis. Aumolertinib, the third-generation Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors (EGFR-TKI), has achieved potent efficacy for patients with EGFRm NSCLC. Besides, the results of phase III registration trial with adjuvant aumolertinb versus placebo is about to be released soon and aumolertinb will be the third EGFR-TKI comprising indication concerning adjuvant therapy worldwide. Therefore, the aim of this study was to evaluate the efficacy of aumolertinib as adjuvant therapy in resected stage I-III NSCLC with high-grade histological patterns.

Methods: Stage I-III NSCLC patients who were pathologically confirmed with high-grade patterns (micropapillary, solid component or complex glands) and underwent radical surgery were enrolled in the study. EGFRm patients were either assigned into aumolertinib group (group A) receiving aumolertinib (110 mg daily) treatment or observation group (group B). Patients with EGFR mutation negative or unknown were under observation allocated in Group C. The primary endpoint was disease-free survival (DFS) by investigator assessment. The safety was also evaluated.

Results: A total of 144 patients were recruited. 92 patients were EGFRm, of whom, 67 were orally administrated aumolertinb in group A and the rest were only observed in group B. 52 patients with EGFR mutation negative or unknown were under observation in Group C. At data cut-off (December,2024), the median follow-up time was 25.5, 39.1 and 39.0 months in Group A, B and C, respectively. In group C, the 3-year DFS rate was 82%. As for EGFRm patients, the 3-year DFS rate of Group A with 84% was significantly better than that of Group B with 64% (p=0.039). Tumor recurrence only occurred in 6 patients in group A. When stratified by stage and the proportion of high-grade patterns, the 3-year DFS rate of Group A with stage I (p=0.029) and those with 5% high-grade patterns(p=0.0017) were also greatly improved than that of group B. In addition, DFS was also superior in Group A 19DEL patients than in Group B (p=0.012). In terms of the analysis of group B and C (both were observation only), the recurrence ratio in EGFRm patients was higher than those with EGFR negative or unknown. No adverse events of grade≥3 occurred during aumolertinib treatment. 10.4% (7/67) of patients experienced treatment-related adverse reactions, the most common of which were pruritus (4.5%) and rash (3%).

Conclusions: Our study was the first to report adjuvant therapy data for aumolertinib as well as third-generation EGFR-TKIs in NSCLC with high-grade patterns. This updated results further revealed the long-term efficacy and safety of adjuvant aumolertinb and provide a solid proof for real-world practice. Moreover, the study confirmed that patients in stage I and those with≥5% high-grade patterns can benefit from aumolertinib therapy. Continuous follow-up is ongoing to investigate further survival outcomes.

Introduction: In the IMPower-010 trial, adjuvant atezolizumab demonstrated a significant improvement of disease-free survival along with a tolerable safety profile in patients with stage IB-IIIA non-small cell lung cancer (NSCLC) and high programmed death ligand-1 (PD-L1) expression. We report real-world safety data of adjuvant atezolizumab in surgically resected NSCLC with PD-L1>50% from the Italian ATLAS registry.

Methods: Clinical data and treatment-related adverse events (TRAEs) were retrospectively collected from patients' medical records and electronic healthcare records. TRAEs were classified according to the Common Terminology Criteria for Adverse Events (CTCAE) version 5.0.

Results: Between July 2022 and August 2024, 132 patients from 43 Italian centers received adjuvant atezolizumab and were included in the analysis. The median age at diagnosis was 65 years (range: 35-80). Most patients were male (65.2%) and current/former smokers (90.9%). Eastern Cooperative Oncology Group (ECOG) performance status (PS) was 0 and 1 in 61.4% and 37.9%, respectively. Adenocarcinoma was the predominant histological subtype (62.1%), with PD-L1 expression ranging between 50% to 89% in 78% and higher than 90% in 22.0% of cases. Molecular analyses were mainly performed using next generation sequencing (63.6%) and all patients were EGFR and ALK wild type. Molecular alterations were identified in 47.7% of cases, with KRAS G12C and non-G12C mutations detected in 15.9% and 18.2% of patients. Lobectomy was performed in 81.1%, pneumonectomy in 6.8%, and both bilobectomy and wedge resection in 6.0% of patients, surgical approach was not reported in 6.1%. According to the 8th TNM staging system, 43.9% had pathological stage IIIA, 40.2% stage IIB, 8.3% stage IIA, and 7.6% stage IIIB. All patients received adjuvant platinum-based chemotherapy. The most common regimens were cisplatin plus vinorelbine (58.3%) and cisplatin plus gemcitabine (24.2%), while 3.9 and 14% of the patients received other cisplatin-based regimens and carboplatin-based combinations, respectively. The median interval from surgery to adjuvant treatment was of 59 days (range 13-270). The median number of adjuvant chemotherapy cycles was 4 (range:1-4). Two patients with pN2 disease underwent adjuvant radiotherapy. With a median follow up of 15.7 months, 54.4% of patients were still receiving adjuvant atezolizumab at the data cut-off. Among those who completed treatment, the median number of cycles was 12.5 (range: 1-20). TRAEs were reported in 33.3%, including skin toxicity (9.1%), diarrhea (8.3%), and increased transaminases (4.5%). Grade ≥3 TRAEs occurred in 15.2%, with diarrhea (3.8%), increased transaminases (2.3%), and enterocolitis (2.3%) being the most frequent. Treatment discontinuation due to TRAEs occurred in 13.6%: diarrhea (5.3%), increased transaminases (2.3%), and enterocolitis (2.3%).

Conclusions: These data are consistent with prior reports confirming the manageable profile of adjuvant atezolizumab in a real-world clinical setting with no new safety signals reported in our analysis.

P1.07.52 Clinicopathologic Risk Score to Guide Adjuvant Chemotherapy in Stage IB NSCLC: Toward Integration of AI-Assessed Tumor Immune Signatures

J. Seo[1], Y.J. Kim[1], J.S. Lee[1], Y.W. Kim[1], J.H. Lee[1], C-T. Lee[1], J.H. Jeon[1], S. Cho[1], K. Kim[1], H.J. Kim[1], J-H. Chung[1], C. Ahn[2], S. Hwang[2], C-Y. Ock[2], S.H. Kim[1]
[1]Seoul National University Bundang Hospital, Seongnam-si/KR ,[2]Lunit, Seoul/KR

Introduction: Adjuvant chemotherapy is recommended for patients with high-risk features in stage IB non-small cell lung cancer (NSCLC), but the definition of 'high risk' remains inconsistent and unstandardized. We aimed to develop a clinicopathologic scoring system for relapse risk and to explore its association with AI-assessed immune signatures derived from histologic slides.

Methods: We analyzed a retrospective cohort of 431 stage IB NSCLC patients. Clinical and pathologic high-risk features were evaluated for disease-free survival (DFS), and a weighted risk score was constructed using multivariable Cox regression. In an exploratory cohort (n=102), immune signatures including immune phenotype, tumor-infiltrating lymphocytes (TILs), and tertiary lymphoid structures (TLSs) were quantified using Lunit Scope IO and correlated with high-risk features.

Results: Patients who received adjuvant chemotherapy (25% of total) were more likely to have high-risk features such as visceral pleural invasion (p<0.001), lymphatic invasion (p=0.003), and aerogenous spread (p=0.003). Although selectively administered to higher-risk patients, chemotherapy showed a favorable trend in DFS (HR 0.55, p=0.26). Poor differentiation was the strongest independent prognostic factor (HR 3.42, p=0.027), followed by trends for visceral pleural invasion (HR 1.08), lymphovascular invasion (HR 1.44), and sublobar resection (HR 1.67). Based on these findings, a clinicopathologic risk score (range: 0-5) was developed, assigning points to poor differentiation (2), lymphovascular invasion (1), sublobar resection (1), and visceral pleural invasion (1). The score effectively stratified patients into low (0-2) vs. high (3-5) risk groups, with high-risk patients (23% of total) showing significantly worse 2-year DFS (97.1% vs 87.6%; HR 3.11, 95% CI 1.34-7.20, p=0.008), and a C-index of 0.67 for DFS across the entire study period. In subgroup analysis, chemotherapy improved 2-year DFS in high-risk patients (92.9% with vs. 84.8% without chemotherapy), while no meaningful benefit was observed in low-risk group (96.9% vs. 97.2%). In the exploratory cohort, immune-cold phenotypes (excluded/desert) were more common in tumors with high-risk features such as lymphovascular invasion, aerogenous spread, and poor differentiation, suggesting a link between immune evasion and aggressive tumor biology. Inflamed phenotypes demonstrated higher TIL and TLS densities compared to excluded/desert phenotypes. However, these immune signatures were not prognostic in this limited dataset.

Conclusions: Our clinicopathologic relapse risk score effectively stratifies stage IB NSCLC patients and may help identify high-risk patients likely to benefit from adjuvant chemotherapy. The observed correlation between immune signatures and high-risk pathology warrants further investigation as complementary biomarkers.

P1.07.53 Aumolertinib as Adjuvant Therapy in I-III EGFRm NSCLC : Also Effective in Patients With Multiple Prognostic Risk Factors

H. Zhang[1], J. Xu[1], P. Meng[1], Z. Ruan[1], Q. Xue[1]
[1]Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai/CN

Introduction: In patients with stage I-III EGFRm NSCLC, the 5-year postoperative recurrence rate remains as high as 50% despite achieving local control through radical surgery (R0 resection), resulting in suboptimal long-term survival. Recurrence risk is multifactorial, including high-grade patterns (e.g.,micropapillary, solid component), high-risk relapse factors (e.g., spread through air space,vascular invasion), advanced age (≥70 yr), and comorbidities (e.g., hypertension, diabetes), all of which significantly increase disease progression risk. However, data on optimized adjuvant therapy for EGFRm NSCLC patients with multiple prognostic risk factors remain limited. This study aims to evaluate the efficacy of aumolertinib as adjuvant therapy in this patient cohort and explore the influence of various adverse factors on clinical outcomes.

Methods: Stage I-III EGFRm NSCLC patients who were pathologically confirmed with at least one prognostic risk factor and underwent radical surgery were enrolled in this study ,followed by adjuvant treatment with aumolertinib 110 mg once daily, The primary endpoint was disease-free survival (DFS) by investigator assessment. The safety was also evaluated.

Results: A total of 52 patients were enrolled, with a median follow-up of 31.0 months as of the data cutoff (March 2025). Eight deaths occurred, with 3-year disease-free survival (DFS) and overall survival (OS) rates of 82.8% and 87.4%, respectively. Subgroup analysis based on individual prognostic risk factor (e.g., age >70 vs. ≤70 years, high-grade patterns, high-risk relapse factors and comorbidities) revealed no statistically significant differences in the efficacy of adjuvant aumolertinib across all subgroups. Further stratification by ACE-27 scores indicated that patients with moderate to severe comorbidities (ACE-27 score 2-3) had comparable DFS (p=0.89) and OS (p=0.73) to those with lower comorbidity burdens (ACE-27 score 0-1). Additionally, in patients with ≥ 2 prognostic risk factors , aumolertinib demonstrated consistent efficacy (all P > 0.1, not statistically significant), regardless of the classification or number of risk factors (table 1).No adverse events of grade≥3 occurred during aumolertinib treatment. 21.3% (11/52) of patients experienced treatment-related adverse reactions, the most common of which were rash (9.62%%) and fatigue (7.69%).

Conclusions: Our study was the first to report adjuvant therapy data for aumolertinib as well as third-generation EGFR-TKIs in NSCLC with multiple prognostic risk factors. The results further confirm the long-term efficacy and safety of adjuvant aumolertinib , supporting its clinical applicability in populations with heterogeneous risk profiles. Notably, therapeutic efficacy remained robust regardless of comorbidity severity, age, or cumulative risk burden. Continuous follow-up is ongoing to further investigate survival outcomes.

Table 1. Subgroup analysis based on prognostic risk factors

Prognostic risk factors			n（%,N=52)	DFS P value	OS P value
Count	Classification

P1.07.54 The Effect of Adjuvant EGFR-TKI Therapy on the Prognosis of Pathological Stage I Invasive Lung Adenocarcinoma With Sensitive EGFR Mutation

Z. Liu, J. Mei
West China Hospital, Sichuan University, Chengdu/CN

Introduction: The prognosis of stage I non-small cell lung cancer (NSCLC) remains significant heterogeneity. It is not clear whether adjuvant EGFR-TKI therapy can reduce the recurrence rate and improve survival in patients with stage I disease, especially stage IA.

Methods: This is a retrospective, single-center, observational, propensity score-matched study that enrolled patients with pathological stage I invasive lung adenocarcinoma with EGFR mutation who underwent surgical treatment. The patients were divided into an observation group and an EGFR-TKI group. Inverse probability of treatment weighting (IPTW) was applied to address baseline characteristic imbalances between the two groups. The primary endpoint was relapse-free survival (RFS), and the secondary endpoints was overall survival (OS). RFS and OS were calculated using the Kaplan-Meier method, and the log-rank test was used to compare differences between the two groups. Stratified analysis was performed according to the risk of recurrence determined by tumor characteristics and surgical procedure.

Results: A total of 819 eligible patients were included in the study. After IPTW, 823 patients were included in the analysis, of which 183 (22.2%) patients were in the EGKF-TKI group and 640 (77.8%) patients were in the observation group. For patients with stage I disease, the 5-year RFS was 92.6% (95% CI, 88.4 to 97.1) in the EGFR-TKI group, compared to 77.0% (95% CI, 73.5 to 80.7) in the observation group (HR = 0.26; 95% CI, 0.15 to 0.46; P < 0.001). For patients with stage IA disease, the 5-year RFS was 98.2% (95% CI, 94.8 to 100) in the EGFR-TKI group, compared to 83.2% (95% CI, 78.6 to 88.1) in the observation group (HR = 0.08; 95% CI, 0.01 to 0.57; P = 0.018). For patients with stage IB disease, the 5-year RFS was 87.4% (95% CI, 80.4 to 95.1) in the EGFR-TKI group, compared to 73.5% (95% CI, 68.7 to 78.6) in the observation group (HR = 0.36; 95% CI, 0.21 to 0.63; P < 0.001). Superior RFS was observed with adjuvant EGFR-TKI therapy in most predefined subgroups. There was no significant difference in OS between the two groups of patients with stage I, stage IA, or stage IB disease. In stratified analysis based on recurrence risk, EGFR-TKI therapy improved 5-year OS but not OS in patients with either stage IA or IB disease, regardless of their recurrence risk.

Conclusions: Our study demonstrates that adjuvant EGFR-TKI therapy improves RFS in patients with stage IA and IB invasive lung adenocarcinoma regardless of their recurrence risk, but the difference in OS is not statistically significant. Given the high cost and potential side effects of these drugs, the benefits of improved RFS must be carefully weighed against the lack of a clear survival advantage.

P1.07.55 Molecular Profiling of Neo-Adjuvant IO Disclosures Residual Cancer Cells in pCR NSCLC: A Single Cell Analysis of CTONG 1804

S-Y.M. Liu[1], S. Dong[1], S-Y. Liu[1], X-N. Yang[1], R-Q. Liao[1], B-Y. Jiang[1], Q. Wang[2], X-S. Ben[3], J-T. Lin[1], H-H. Yan[1], L-X. Yan[4], Q. Nie[1], H-Y. Tu[1], B-C. Wang[1], J-J. Yang[1], Q. Zhou[1], W-C. Luo[1], C. Huang[1], X. Zhang[5], H. Li[5], J. Wu[5], W-Z. Zhong[1], Y-L. Wu[1]
[1]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN ,[2]Department of Thoracic Surgery, Zhongshan Hospital, Fudan University, Guangzhou/CN ,[3]Department of Thoracic Surgery, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University,, Guangzhou/CN ,[4]Department of Pathology, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN ,[5]Kanghui Biotech Co. LTD, Beijing/CN

Introduction: We recently reported the clinical findings from a phase II trial of neoadjuvant immunochemotherapy (IO) in untreated patients with resectable non-small cell lung cancer (NSCLC) (CTONG1804). This trial provided an opportunity to investigate the correlation of pathological response and early immune microenvironment during neoadjuvant IO.

Methods: We conducted single-cell RNA sequencing (scRNA-seq) on fresh tumor tissue at pre- and post-IO treatment. Multi-omics sequencing was also used in this exploratory study, that included bulk RNA sequencing and tumor-informed MRD sequencing.

Results: Twenty-one patients were enrolled. The pathological complete response (pCR) rate was 42.9% (9/21). Unexpectedly, a total of 143 cancer cells with genome alterations were identified in six (6/9=66.7%) patients with pCR (Fig 1). Only one pCR patient presented MRD positive within one month after surgery, who had the highest number of cancer cells. These residual cancer cells exhibited reduced proliferative capacity and diminished stem cell-like features but retained epithelial-mesenchymal transition (EMT) markers, suggesting metastatic potential and drug resistance (Fig 2). Elevated antigen presentation pathways, particularly involving CD74-MHC class II, were observed in pCR cancer cells, alongside a significant reduction in tumor neoantigen burden. When comparing the immune cells of different pathological response, we found that conventional dendritic cell type 2 (cDC2) emerged as a critical antigen-presenting cell subtype in pCR patients, enhancing T-cell activation and promoting immune response. Reduced CD4-Treg3 populations correlated with improved treatment outcomes, while CD8-MAIT cells exhibited functional plasticity, transitioning from tumor-promoting to tumor-rejecting phenotypes post-therapy.

Conclusions: Our study highlights the persistence of residual cancer cells even in pCR patients and identifies key immune cell subsets, such as cDC2 and CD8-MAIT cells, that play pivotal roles in modulating anti-tumor response. These findings provide valuable insights into the mechanisms of immune activation and suppression in NSCLC and suggest potential biomarkers and therapeutic targets for optimizing neoadjuvant immunochemotherapy.

P1.07.56 Combining Lymph Nodes and Tumor Radiomics Enhances Immunotherapy Efficacy Prediction in Non-Small Cell Lung Cancer

H. Zhou[1], C. Li[1], S. Wu[1], L. Yao[1], W. Zhan[1], M. Weng[1], C. Cai[1]
[1]Department of Thoracic Surgery, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou [510080], China., Guangzhou/CN

Introduction: Immune checkpoint inhibitors (ICIs) are widely used in non-small cell lung cancer (NSCLC), but their application is associated with adverse effects, necessitating the exploration of more effective biomarkers. Numerous studies have demonstrated the unique role of radiomics in early cancer diagnosis, assessment of pathological treatment response, and prediction of lymph node metastasis. Although lymph nodes play a critical role in immunotherapy, current radiomics studies often neglect lymph node radiomic features when predicting ICI efficacy. The relationship between radiomic features of subcarinal lymph nodes and ICI efficacy in NSCLC remains underexplored. This study aims to investigate the association between radiomic features of pulmonary lesions and subcarinal lymph nodes in NSCLC patients and their response to immunotherapy, with the goal of predicting pathological complete response (pCR).

Methods: This study retrospectively analysed NSCLC patients (n=208) who received immunotherapy from January 2016 to December 2020 at Guangdong Provincial People's Hospital, and the external validation cohort consisted of a total of 38 patients from Jiangxi Provincial Cancer Hospital. Radiomic features were extracted by 'PyRadiomics' software package. Five machine learning models were constructed using a two-stage optimisation strategy to filter the features, and their performance was evaluated and compared.

Results: The study included 246 NSCLC patients from two independent centers, divided into a training cohort (TC), internal validation (IV), and external validation (EV) cohorts. The logistic regression model demonstrated optimal performance. The AUC values for the radiomic model combining primary lesions and peritumoral regions were 0.69, 0.54, and 0.44 in TC, IV, and EV, respectively. When incorporating subcarinal lymph node radiomic features, the AUC values improved to 0.72, 0.51, and 0.54. Further integration of peri-lymph node features yielded AUC values of 0.70, 0.69, and 0.52 across the three cohorts.

Conclusions: The multimodal predictive model combining radiomic features from primary lesions, peritumoral regions, subcarinal lymph nodes, and peri-lymph node areas shows potential for predicting NSCLC immunotherapy efficacy. This approach holds clinical significance for guiding therapeutic strategies.

P1.07.57 Alterations in the Gut Microbiota and Metabolites in Patients With Liver Injury Induced by Third-Generation EGFR-Targeted Drugs

J-X. Li, D. Zang, J. Chen
THE SECOND HOSPITAL OF DALIAN MEDICAL UNIVERSITY, Dalian/CN

Introduction: Third-generation EGFR-TKI is currently the first-line treatment option for patients with EGFR-mutated NSCLC. Drug-induced liver injury (DILI) is one of the common reasons for drug withdrawal in clinical practice, and there are no specific therapeutic drugs at present. Dysregulation of intestinal microbes can lead to disruption of the intestinal barrier and microbial translocation, while changes in microbial metabolites may cause or aggravate DILI. Therefore, it is of great significance to study the mechanism of intestinal microbes in third-generation EGFR-TKI-related liver injury and explore potential strategies to interfere with drug toxicity by regulating the flora.

Methods: We collected stool specimens from 18 patients with liver injury after third-generation EGFR-targeted therapy at baseline and at the time of liver injury, of which 5 were not collected at the time of liver injury. We conducted metagenomic and metabolomic study sequencing to compare the differences in gut microbiota and metabolites between the two groups of samples.

Results: Among all the samples, there were 18 cases in the Dbase group and 13 cases in the Doccur group. Our analysis revealed significant differences in the gut microbiota and metabolites between the two groups of samples. Species-based α diversity analysis revealed significantly lower ACE, Chao1 (both P=0.00065) and Shannon indices (P=0.0097) in fecal specimens during liver injury compared to baseline, indicating reduced microbial species richness and diversity. We found that the Intestinimonas, Anaeromassilibacillus, Ruminiclostridium, and Robinsoniella decreased in the Doccur group. Metabolomics analysis showed that Octadecenoic acid, 4-Hydroxyphthalide, 2,3-Dinor-8-iso prostaglandin F2alpha, Gibberellin A20, 5-Cholesten-3beta-25-diol-3-sulfate, etc decreased in the Doccur group. KEGG metabolic pathway analysis of the two groups of differential metabolites showed that arabinogalactan biosynthesis, glycolysis, and diterpene biosynthesis had significant differences in synthesis and secretion pathways.

Conclusions: Our findings suggest that the abundance of the gut microbiota and its metabolites in patients with liver injury following EGFR-targeted drugs differ from baseline. Intestinal flora and its metabolites can be used as an effective means to predict the adverse reactions of molecularly targeted drugs.

Introduction: Nivolumab plus ipilimumab in combination with 2 cycles of platinum-based chemotherapy is actually a standard of care in the first-line treatment of metastatic non-small cell lung cancer (NSCLC). NICReWo is an Italy-wide, multicenter, observational, ambispective study, designed to collect real-life data during the early post-market authorization approval period of the combination nivolumab plus ipilimumab plus chemotherapy. This is the first report of the retrospective part of the study.

Methods: Data were retrospectively collected starting from January 2022, co-primary endpoints were to evaluate progression-free survival (PFS) and overall survival (OS) in a real world patient population. Secondary endpoints were overall response rate (ORR), duration of treatment and incidence of treatment-related adverse events (AEs). All data obtained for this study were recorded with an Electronic Data Capture (EDC) system using eCRFs (RedCap platform).

Results: 192 patients were enrolled at the time of data cut-off (March 31, 2025) across 9 Italian sites. Median age was 67.9 years old (range: 33-86). The median duration of treatment was 5.67 months (95% CI, 1.81-7.37), corresponding to a median of 6.53 cycles; 51 patients are still ongoing with the treatment without disease progression. After a median follow-up of 20 months (95% CI, 11.0-28.0) the median PFS was 5.5 months (95% CI, 2.8-12.4); 12-months PFS rate was 26.5% (95% CI, 19.3-34.1). Median OS was 9.8 months (95% CI, 4.50-20.1); 12-months OS rate was 45.6% (95% CI, 36.7-54.1). ORR was 29.2%. There were no significant differences in survival based on PD-L1 status (tumor proportional score TPS < 1 versus 1-49%), histology (squamous versus non squamous), presence of liver and brain metastases, KRAS mutational status.Any-grade AEs occurred in 109 patients (56.8%) and Grade ≥ 3 in 21 patients (10.9%). Most common Grade ≥ 3 AEs were neutropenia, colitis and hepatotoxicity. Any-grade immune-related AEs (irAEs) occurred in 68 patients (35.4%) and Grade ≥ 3 in 15 patients (7.8%). Most common Grade ≥ 3 irAEs were colitis and hepatotoxicity. 19 patients discontinued permanently treatment because of toxicity. OS and PFS were significantly higher in patients who have experienced irAEs compared to patients without irAEs, with 12-months OS of 68.1% compared to 12-months OS of 32.1% respectively.Subsequent therapies were administered for 49 patients (25.5%), in particular 19 patients received platinum-based chemotherapy, 16 patients monochemotherapy, 11 patients target therapies and 3 patients radiotherapy.

Conclusions: This study helps address an unmet clinical need for a real world population treated with the combination of nivolumab plus ipilimumab with 2 cycles of platinum-based chemotherapy. This is the first report and survival data are still immature, while the safety profile seems to be in line with was reported in the literature. Our real world study population, compared with patients enrolled in the CheckMate 9LA trial, is characterized by a 3-years higher median age, inclusion also of ECOG PS ≥ 2 patients, higher prevalence of brain metastases, absence of PD-L1 overexpressed patients and lower rate of squamous histology. The prospective part of the study is still ongoing.

P1.11.02 Impact of Prophylactic Use of Cardioprotective L-Carnitine on First-Line Chemoimmunotherapy in Advanced NSCLC: A Cohort Study

C.B. Han, L. Sun, J. Ma, S. Zhang, L. Huang, X. Han
Shengjing Hospital of China Medical University, Shenyang/CN

Introduction: L-Carnitine, a critical mediator of fatty acid metabolism and mitochondrial energy production, has shown potential in modulating metabolic profiles, immune responses, and gut microbiota dynamics. Preclinical evidence suggests its role in mitigating chemotherapy-induced toxicity and influencing tumor microenvironments. This study investigates whether prophylactic L-carnitine supplementation impacts outcomes in advanced non-small cell lung cancer (NSCLC) patients receiving first-line chemoimmunotherapy (PD-1 inhibitor plus platinum-based chemotherapy).

Methods: In this retrospective cohort study, 223 patients with advanced NSCLC treated at Shengjing Hospital between January 2019 and December 2024 were stratified into two groups: the intervention group (n=117) received L-carnitine alongside chemoimmunotherapy, while the control group (n=116) received chemoimmunotherapy alone. Primary endpoints included progression-free survival (PFS), overall survival (OS), objective response rate (ORR), and safety. The study was approved by the Ethics Committee of Shengjing Hospital.

Results: Baseline covariates, including age, sex, smoking status, hypertension, coronary artery disease, and Charlson Comorbidity Index (CCI), were well-balanced between the two groups. After a median follow-up of 17.7 months, median PFS was comparable between the groups (9.7 vs. 10.4 months; HR=1.11, 95% CI: 0.79-1.56; p=0.56). Median OS was also similar (41.2 vs. 37.7 months; HR=1.15, 95% CI: 0.74-1.79; p=0.54), with 1-year survival rates of 80.3% vs. 78.4% and 2-year survival rates of 60.4% vs. 69.6%, respectively, in the intervention and control groups (all p>0.05). ORR showed no significant difference between the groups (59.8% vs. 60.3%; p=0.99). Subgroup analyses revealed no PFS or OS benefit across clinical variables. Safety profiles were similar between the two groups, with no significant difference in cardiac-related adverse events. Immune-related myocarditis was observed in 6.8% of the intervention group and 8.6% of the control group (p=0.63). No grade ≥3 immune-related myocarditis was observed in either group.

Conclusions: Prophylactic L-carnitine did not provide additional survival benefits or enhance safety in advanced NSCLC patients undergoing first-line chemoimmunotherapy. These findings suggest that routine use of L-carnitine may not be warranted in this context. Prospective studies are necessary to further explore its potential role and identify any specific subgroups that might benefit.

P1.11.03 Long-Term Efficacy of Immune Checkpoint Inhibitors in Pulmonary Cancer With Rhabdoid Features: A Single-Center Retrospective Analysis

M-L. Meyer, A. Serena, L. Gros, M. Maillard, K. Abdelhamid, M. Christofis, N. Ferahta, V. Mosimann, A. Stamatiou, N. Mederos, H. Bouchaab, C. Sempoux, S. Peters
CHUV, Lausanne/CH

Introduction: Pulmonary cancers with rhabdoid features (PCRF) are exceedingly rare, with only 44 cases documented. PCRF typically exhibit aggressive behavior and poor prognosis. Molecular data on pulmonary rhabdoid tumors remain scarce, with unreported PD-L1 status, and reports of SMARCA4, KRAS G12D and EGFR exon 19 alterations. The efficacy of immune checkpoint inhibitors (ICIs) is poorly documented in PCRF. Here, we report three patients with PCRF treated with ICIs.

Methods: We retrospectively reviewed of thoracic oncology databases at our institution to identify patients with PCRF treated with ICIs. Informed consent was obtained from all included patients. Clinical data were analyzed and pathology slides were re-evaluated. A comprehensive literature review was performed using PubMed and Google Scholar to identify previously reported cases of PCRF.

Results: We identified three patients treated for PCRF. The first, a 53-year-old male with a 20-pack-year smoking history, presented with epigastric pain and melena. Imaging revealed a right lung mass, bilateral adrenal nodules, mesenteric lymphadenopathy, tonsillar enlargement, and small bowel lesions (stage IVB). Pathological examination confirmed non-small cell carcinoma with rhabdoid features, PD-L1>90%. The patient achieved a complete response to pembrolizumab monotherapy (200 mg every 3 weeks). After 4 years of treatment, the patient developed probable treatment-induced psoriasis, treated with triamcinolone acetonide. Pembrolizumab could be continued. As of today, the patient remains disease-free, seven years after treatment initiation. The second patient is a 64-year-old male with a 50-pack-year smoking history and controlled HIV. Presenting with fatigue and weight loss, imaging revealed lesions in the jejunum, adrenal gland, and lungs (stage IVB). Surgical resection of the jejunal lesion identified an undifferentiated tumor with rhabdoid and epithelioid features. Molecular testing detected a KRAS G12C mutation, PD-L1 100%. Treatment with carboplatin, paclitaxel, and pembrolizumab led to a complete response. After 18 months, isolated adrenal gland activity on the PET-CT prompted stereotactic radiotherapy (36 Gy in 6 fractions). Pembrolizumab was continued, and three and a half years from treatment initiation, the patient remains disease-free. The third patient, a 65-year-old woman with a 30-pack-year smoking history and prior nephrectomy for renal clear-cell carcinoma, presented with a pulmonary nodule and mediastinal lymphadenopathy (stage IIIA). Mediastinal biopsy confirmed non-small-cell carcinoma with rhabdoid features, PD-L1 95%. She underwent a lobectomy and received 4 cycles of adjuvant chemotherapy (carboplatin and pemetrexed). After one year, she presented hypermetabolic mediastinal lymphadenopathy. A biopsy revealed a NSCLC, NOS, PD-L1 3%. She received concurrent chemoradiotherapy (carboplatin and vinorelbine), followed by durvalumab consolidation. One year later, pericardial and pleural effusions developed, cytologically consistent with metastatic renal carcinoma. Despite initiating cabozantinib, she succumbed to disease progression after three months.

Conclusions: Our experience highlights the potential efficacy of ICIs in treating PCRF, particularly with high PD-L1 expression. Notably, this is the first report of prolonged responses to ICIs in these patients. Two patients with metastatic disease achieved durable complete responses and remain disease-free years after treatment. All patients with PCRF had high PD-L1 expression. Further research should focus on the molecular characterization of PCRF and identify therapeutic targets.

P1.11.04 Prediction of Overall Survival in Lung Cancer Patients With Different Organ Metastases: A SEER Population-Based Cohort Study

K. Qin[1], A.A. Qin[2]
[1]MDanderson, Houston/TX/USA ,[2]Rutgers University, Newark/NJ/USA

Introduction: Distant organ metastasis is a common event in lung cancer (LC). However, the metastatic pattern of different organ of LC and its effect on prognosis have not been comprehensively elucidated. This study aimed to explore the distant metastasis pattern and construct nomograms predicting the metastasis and survival of LC patients using the Surveillance, Epidemiology, and End Results (SEER) database.

Methods: Lung cancer (LC) data from 586,674 patients diagnosed between 2010 and 2021 were obtained from the SEER database. Patient records were excluded if the lung was not the first primary site, overall survival (OS) was less than 1 month, baseline clinicopathological data were unavailable, survival time was missing, or the patient was younger than 18 years old. The relationship between distant metastatic sites and overall survival was retrospectively analyzed. In addition, 12 machine learning modelswere trained and evaluated to predict occurrence of death based on different metastatic patterns. Model performance was assessed using ROC curves, precision-recall (PR) curves, calibration plots, and decision curve analysis (DCA). The best-performing model was further interpreted using SHAP (SHapley Additive exPlanations), with results visualized through summary plots, bar charts, and circular radar diagrams.

Results: A total of 235,290 patients were finally included for data analysis. 74,526 (31.67%) patients had different degrees of distant metastasis, including 45758(19.45) patients with single organ metastases and 20573(8.74%), 8195(3.48%) multiple (≥3) organ metastases, and 14,3635(61.05%) patients had no distant metastasis. Patient without distant organ metastasis had a significantly longer survival than patients with1 or 2 or 3 or 4 organ metastasis[mOS: 55m (95%CI 54m-55m) vs10m (95%CI 10m-10m), vs 7m (95%CI 6m-7m), vs 6m(95%CI 6m-7m), vs 5m(95%CI 5m-6m), P<0.0001]. Among patients with mono-organ metastasis, the median OS of patients with liver and bone metastasis[mOS: 8m (95%CI 8m-9m)] was significantly shorter than those with brain metastasis (mOS:9m, 95%CI 9m-9m) or lung metastasis(mOS:14m, 95%CI 14m-15m),7 months (95%CI 7m-7m), 6 months (95%CI 5m-6m) respectively, and the difference was significant (P<0.0001); Among those deceased patients(N=151256), 83.26% patients (N=125933) eventually died of lung cancer. In addition, In patients with bone metastasis: GBT achieved the best performance (AUC=0.851,95%CI 0.841-0.862). Top SHAP predictors included year of diagnosis, pathology, treatment status, age, and site of metastasis. In patients with brain metastasis: AdaBoost performed best (AUC=0.851,95%CI 0.841-0.861), with top predictors being year of diagnosis, number of organ metastases, pathology, age, and treatment. In patients with liver metastasis: GBT again showed best performance (AUC=0.850,95%CI 0.835-0.866), with important features including year of diagnosis, pathology, tumor size, age, and treatment. In patients with lung metastasis: GBT was optimal (AUC=0.847,95%CI 0.836-0.859), with SHAP analysis highlighting year of diagnosis, sex, site of metastasis, age, and pathology as key predictors.

Conclusions: Different metastatic patterns at diagnosis in lung cancer are associated with distinct survival outcomes. Patients with liver/bone metastases exhibit significantly shorter overall survival. This study developed novel, machine learning models capable of accurately predicting mortality across organ-specific metastatic patterns, which will aid physicians in making individualized treatment decisions in lung cancer management.

P1.11.05 Efficacy and Multi-Omics Insights of Immune Checkpoint Inhibitors in NSCLC With Leptomeningeal Metastasis

L-B.B. Tang[1,2,3], Y-S. Li[2,3], C-R. Xu[2,3], K. Yin[2,3], H-B. Gao[2,3], J-X. Lin[2,3], Y-L. Sun[2,3], E-E. Ke[2,3], X-C. Zhang[2,3], H-Y. Tu[2,3], J-J. Yang[2,3], H-J. Chen[2,3], B-C. Wang[2,3], F-M. Xiao[2,3], W-Z. Zhong[2,3], Y. Pan[2,3], H-H. Yan[2,3], L. Zeng[2,3], Y-L. Wu[2,3], Q. Zhou[2,3], M-M. Zheng[2,3]
[1]School of Medicine, South China University of Technology, Guangzhou/CN ,[2]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou, Guangdong/CN ,[3]Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou, Guangdong/CN

Introduction: Patients with leptomeningeal metastasis (LM) are frequently excluded from clinical trials due to poor overall survival (OS) and compromised performance status. Evidence on immune checkpoint inhibitors (ICIs) in non-small cell lung cancer (NSCLC) with LM is limited. Hence this real-world study aimed to show the efficacy of ICI treatment for LM and used multi-omic analysis with cerebrospinal fluid (CSF) and plasma to explore potential predictive biomarkers.

Methods: This study enrolled 72 patients with NSCLC and LM receiving ICIs at Guangdong Lung Cancer Institute from December 2017 to April 2024. Clinical information, treatment evaluation and survival outcomes were collected. Patients were stratified into response and non-response cohorts based duration of response. Multi-omic profiling, using proteomic, metabolomic, and next-generation sequencing analyses was conducted on CSF and plasma samples collected before and after ICI treatment.

Results: Among the 72 enrolled patients, 93% demonstrated ECOG PS ≤1, 51.4% harbored driver gene mutations, and 54.2% received ≥2 lines systemic therapy. 28% exhibited neurological symptoms. Subsequently, 84.7% received ICI-based combination therapy. The median OS was 19.2 months (95% CI: 0.6-74.7). Among 66 patients with evaluable progression-free survival (PFS), the median PFS was 4.3 months (95% CI: 0.4-57.6), significantly influenced by age (P=0.02) and driver gene status (P=0.01). Among them, 12 patients achieved long-term benefits from ICIs, with PFS exceeding 12 months, including 3 surpassing 24 months. The response cohort demonstrated markedly prolonged OS compared to non-response cohort (21.7 vs. 4.9 months, P<0.0001). Prior use of antiangiogenic drugs affected response to ICI significantly (p=0.03). Proteomic analysis identified MCP-3, IP-10, IL-13, and GZM as differentially expressed proteins in CSF between responder and non-responder. Notably, elevated MCP-3 levels in both CSF (P=0.02) and plasma (P=0.02) were strongly associated with response. Further analysis revealed significant enrichment in immune cell chemotaxis and migration, chemokine signaling, host defense response, and vascular homeostasis regulation pathways. CSF and plasma exhibit relatively distinct differential metabolites, without consistent enrichment pathways. CSF circulating tumor DNA positive detection was also significantly associated with response (P=0.02) but showed no statistical association with survival.

Conclusions: This study revealed that selected patients with LM derived benefits from ICI combination treatments. Multi-omics analysis identified MCP-3 as a potential efficacy biomarker for ICI treatment. Further prospective studies are warranted to explore the use of ICIs for LM.

P1.11.06 Risk Factors and Prognosis of Immune Checkpoint Inhibitor-Induced Pneumonia in Lung Cancer With Interstitial Lung Disease

T. Ueda, S. Nanjo, T. Shimizu, S. Nomura, S. Arai, K. Kase, N. Terada, H. Koba, S. Watanabe, Y. Tambo, S. Yano
Kanazawa University Hospital, Ishikawa/JP

Introduction: Lung cancer patients with interstitial lung disease (ILD) are known to be associated with a higher frequency of immune checkpoint inhibotor (ICI) induced pneumonitis. Even in such a population, ICI treatment sometimes results in long-term survival. This study aimed to determine the risk factors and prognosis of ICI-induced pneumonitis in lung cancer patients with ILD treated with ICIs.

Methods: We retrospectively analyzed 12 lung cancer patients with ILD out of 231 patients treated with ICIs at Kanazawa University Hospital from January 2019 to March 2023.

Results: The patient background was Male/Female: 10/2 cases; Smoking history: all cases; Median age (range): 70 (53-84) years; Histological type: Adenocarcinoma/Squamous cell carcinoma/Small cell lung cancer: 6/4/2 cases; Stage III/IV/postoperative relapse: 3/5/4 cases; 1st / 2nd line treatment: 8/4 cases. The background ILD imaging pattern was UIP: 4 cases, probable UIP: 3 cases, fNSIP: 3 cases, and RB-ILD: 2 cases. ICI-induced pneumonitis was observed in four patients (33%), but there was no Grade 3 or higher pneumonitis. Of the four cases with ICI-induced pneumonitis, 2 cases had honeycomb lung and 1 case had high antinuclear antibody levels, but %VC was better than 80% in all four cases. The proportion of patients with ICI-induced pneumonitis had high SP-D levels compared with patients without ICI-induced pneumonitis (75% and 0% respectively; P = 0.003 by Fisher's exact test). No significant difference was found in LDH, CRP, or KL-6 levels between the two groups. The median overall survival was 27.4 months in patients with ICI-induced pneumonitis and 12.8 months in patients without ICI-induced pneumonitis (p = 0.13).

Conclusions: When ICIs are used for lung cancer patients with ILD, honeycomb lung, and a high SP-D level could be considered risk factors for ICI-induced pneumonitis. The prognosis was not worse in patients who developed mild ICI-induced pneumonitis.

Introduction: Immune checkpoint inhibitors (ICIs) have become the standard treatment for advanced non-small cell lung cancer (NSCLC). Radiotherapy (RT) enhances local disease control and has immunomodulatory effects, making its combination with ICIs a potential therapeutic strategy. This study investigates how RT intent (palliative vs. radical) and sequencing with ICIs affect overall survival (OS) and progression-free survival (PFS) in patients from the Spanish Lung Cancer Group's Thoracic Tumor Registry (TTR).

Methods: The TTR is a multicenter, observational cohort study of lung cancer in Spain. This retrospective analysis adhered to the Declaration of Helsinki and was approved by the Ethics Committees of all participating centers. The registry was authorized as a non-interventional study by the Spanish Medicines Agency. A total of 2,179 patients with stage IV NSCLC diagnosed at 66 Spanish centers between March 2009 and May 2023 and receiving ICIs—either as monotherapy or with chemotherapy (CT) in the first or second line—were included.

Results: Among 2,179 patients, 475 (21.8%) received RT—88.0% for palliative intent and 12.0% for radical intent. The most common irradiation sites included bone (45.4%), the central nervous system (33.3%), and the lung (14.4%). The median OS (mOS) was 19.4 months for the ICI group, 17.3 months for the ICI/RTpalliative group, and 27.3 months for the ICI/RTradical group (p=0.002). Compared to the ICI/RTpalliative group, patients treated with ICI (HR=0.80, 95% CI: 0.70-0.91) or ICI/RTradical (HR=0.67, 95% CI: 0.47-0.96) had better survival. The median PFS (mPFS) was 6.0 months for the ICI group, 4.6 months for the ICI/RTpalliative group, and 8.7 months for the ICI/RTradical group (p=0.00022). Patients receiving ICI/RTpalliative had a significant worse prognosis than those in the ICI group (HR=1.29, 95% CI: 1.14-1.45). Regarding treatment sequencing, 14.9% patients received ICI before RT (ICI/RTseq), 39.6% concomitant ICI/RT (ICI/RTco), 35.8% RT before ICI (RT/ICIseq), and 9.7% followed a mixed sequence (ICI/RTmix). The mOS was 19.4 months for the ICI group, 13.3 months for the ICI/RTseq group, 20.3 months for the ICI/RTco group, 15.6 months for the RT/ICIseq group, and 18.7 months for the ICI/RTmix (p=0.00019). Compared to the ICI group, patients receiving ICI/RTseq treatment (HR=1.76, 95% CI: 1.35-2.30) or RT/ICIseq (HR=1.26, 95% CI: 1.03-1.54) were associated with worse survival. The mPFS was 6.0 months for the ICI group, 2.9 months for the ICI/RTseq group, 5.9 months for the ICI/RTco group, 5.1 months for the RT/ICIseq group, and 3.9 months for the ICI/RTmix (p<0.0001). Patients receiving ICI/RTseq (HR=1.92, 95% CI: 1.48-2.48), RT/ICIseq (HR=1.23, 95% CI: 1.03-1.47), or ICI/RTmix (HR=1.56, 95% CI: 1.14-2.13) had a worse prognosis than those in the ICI group.

Conclusions: This study highlights the impact of RT intent and sequencing on survival outcomes in advanced NSCLC patients receiving ICIs. Radical RT and concurrent ICI/RT were associated with improved outcomes, while palliative RT and sequential approaches correlated with worse prognosis. These findings support the need for optimized treatment strategies integrating RT and ICIs to enhance patient outcomes.

P1.11.08 Peripheral Inflammatory Biomarkers Predict Immunotherapy Retreatment Outcomes in Advanced NSCLC

J. Zhong
Shanghai Chest Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai/CN

Introduction: The rechallenge of immune checkpoint inhibitors (ICIs) has emerged as a promising therapeutic strategy for advanced non-small cell lung cancer (NSCLC). However, the absence of reliable biomarkers to identify patients most likely to benefit from ICIs rechallenge remains a critical gap in clinical practice.

Methods: This retrospective study included 113 patients with advanced NSCLC who underwent ICI retreatments at the Chest Hospital Affiliated with Shanghai Jiao Tong University School of Medicine between July 2016 and February 2022. The analysis evaluated associations between PD-L1 expression, clinical characteristics, immune-related adverse events (irAEs), and peripheral blood inflammatory markers—including the systemic immune-inflammation index (SII) and the prognostic nutritional index (PNI)—with the efficacy of ICI retreatments.

Results: Progression-free survival after initial immunotherapy (PFS1) was significantly associated with overall survival following ICI retreatments (OS2, P = 0.0020). Notably, PFS1 emerged as a potential predictive marker for patient response to ICI rechallenge (P < 0.001). Patients who experienced irAEs during retreatment demonstrated improved PFS2 (P = 0.0033) and OS2 (P = 0.0006), with severe irAEs correlating with further enhanced survival outcomes (PFS2: P = 0.0156; OS2: P = 0.0361). Moreover, patients with low levels of inflammatory markers, as determined by the combined SII-PNI score, exhibited significantly improved OS2 (P = 0.0097). Multivariate analysis confirmed the SII-PNI score as an independent prognostic factor (P = 0.025), underscoring its utility in stratifying patients based on risk and likely benefit from ICI retreatments. Elevated inflammatory markers were associated with poorer prognosis, suggesting that systemic inflammation contributes to diminished therapeutic efficacy.

Conclusions: These findings highlight the combined SII-PNI score as a novel and clinically valuable biomarker for predicting outcomes in advanced NSCLC patients undergoing ICI retreatments.

P1.11.09 SBRT Combined With Tislelizumab and Granulocyte-Macrophage Colony-Stimulating Factor in Advanced NSCLC Progressing on Immunotherapy

G. You, L. Zhu, L. Zheng
Department of Radiation Oncology, Taizhou Cancer Hospital, Taizhou/CN

Introduction: The combination of immunotherapy and chemotherapy has become the first-line standard treatment for advanced Non-Small Cell Lung Cancer (NSCLC). However, effective therapies are limited once immunotherapy resistance develops.Stereotactic body radiotherapy (SBRT) can effectively destroy tumor cells in the radiation area and can mediate an immune response through the abscopal effect. Granulocyte-macrophage colony-stimulating factor (GM-CSF) can also enhance antitumor immune responses by inducing the maturation of dendritic cells (DCs).

Methods: We conducted a Single-Arm Phase II study (ChiCTR2100047048) to assess the efficacy of SBRT in combination with Tislelizumab and GM-CSF for advanced NSCLC patients who have progressed on immunotherapy. This study prospectively recruited 10 eligible patients who initially underwent SBRT (24Gy/3F or 25Gy/5F), followed by a combination therapy with GM-CSF (150 μg for 2 weeks) and Tislelizumab (200mg, Q3w). Subsequently, patients received maintenance therapy with tislelizumab till progression or intolerable toxicity. The primary endpoint was Objective Response Rate (ORR), and secondary endpoints included Progression-Free Survival (PFS), tumors outside the irradiated fields (abscopal response rate, ASR), and safety.

Results: By 1 July 2024, 10 patients had been enrolled, with a median follow-up time of 11.7 months [IQR: 7.18-20.15 months]. The ORR and Disease Control Rate (DCR) were 30% and 70%, respectively. The ASR was 20% and the median PFS was 6.73 months [IQR: 5.48-7.99 months]. For the safety outcomes, mild treatment-related adverse events (AEs) occurred in 60% of patients, and one patient experienced grade ≥3 immune-related rash.

Conclusions: The study suggests that the integration of SBRT with Tislelizumab and GM-CSF may augment immunotherapy efficacy, presenting a promising therapeutic approach for advanced NSCLC patients following immunotherapy resistance.

P1.11.10 Serum Neopterin and Mortality in Lung Cancer Patients Treated With Immune Checkpoint Inhibitors

M. Spisarova, A. Zemankova, H. Studentova, V. Kucerova, D. Friedecky, B. Melichar
University Hospital Olomouc, Olomouc/CZ

Introduction: The advent of immune checkpoint inhibitors has transformed the management of patients with lung cancer. Immunotherapeutic agents exhibit antitumor activity through the stimulation of immune system, and, in contrast to other targeted therapies, the effect of immunotherapy does not manifest immediately, but only with some delay as time may be needed for the activation of the immune response. Consequently, immunotherapy may fail event in the presence of biomarkers predicting high likelihood of response if the expected survival is shorter than the time needed to obtain a response. Clinical parameters like performance status are commonly used to predict short-term survival, but there is an unmet medical need for laboratory parameters in this setting. Neopterin is a biomarker of systemic immune activation that has been associated with prognosis across the range of solid tumors.

Methods: Serum neopterin, creatinine, C-reactive protein (CRP) and peripheral blood cell count were studied before and during treatment with immune checkpoint inhibitors administered as monotherapy or in combination in 37 lung cancer patients.

Results: Serum neopterin/creatinine ratio (196 ± 73 vs. 387 ± 194 µmol/mol creatinine; p = 0.014), CRP (34.7 ± 31.3 vs.79.7 ± 51.1 mg/l; p = 0.032) and neutrophil count (6.4 ± 2.5 vs. 8.9 ± 2.6 x 109/l; p = 0.048) were significantly lower and hemoglobin was significantly higher (119 ± 27 vs. 106 ± 19 g/l; p = 0.029) in patients who survived for more than 4 months from the start of the therapy compared to patients who died by that time. A significant correlation was observed between serum neopterin/creatinine ratio and CRP (Spearman rank correlation coefficient 0.63; p < 0.0001), hemoglobin (-0.38; p = 0.021), thrombocyte (0.34; p = 0.040), leukocyte (0.34; p = 0.041) and neutrophil (0.36; p=0.029) counts. No significant changes in the parameters examined were observed during the course of therapy.

Conclusions: Serum neopterin/creatinine ratio was almost twice higher in patients who died during the first 4 months of therapy. Neopterin may be useful as a biomarker to identify patients who are unlikely to benefit from immunotherapy.

P1.11.11 Survival Impact of Pneumonitis in Older Patients With Non-Squamous NSCLC Treated With Pembrolizumab and Pemetrexed: Insights From CJLSG1901

Y. Kogure[1], H. Hashimoto[1], H. Daga[2], Y. Goto[3], T. Yamada[4], T. Kimura[5], S. Miura[6], H. Yasui[7], N. Yamamoto[8], H. Saka[9], M. Kondo[3]
[1]NHO Nagoya Medical Center, Nagoya/JP ,[2]Osaka City General Hospital, Osaka/JP ,[3]Fujita Health University, Toyoake/JP ,[4]Kyoto Prefectural Univeristy of Medicine, Kyoto/JP ,[5]Tosei General Hospital, Seto/JP ,[6]Niigata Cancer Center Hospital, Niigata/JP ,[7]Toyohashi Municipal Hospital, Toyohashi/JP ,[8]Wakayama Medical University, Wakayama/JP ,[9]Matsunami General Hospital, Kasamatsu/JP

Introduction: Pembrolizumab combined with pemetrexed has shown efficacy in older patients (aged ≥75 years) with metastatic non-squamous non-small cell lung cancer (NSCLC) and a PD-L1 tumor proportion score (TPS) <50%. However, treatment-related pneumonitis remains a concern, and its impact on clinical outcomes is not fully understood. This post hoc analysis examined the effect of pneumonitis on the efficacy and treatment exposure in the CJLSG1901 study, with a focus on differences in baseline patient characteristics.

Methods: Subgroup analyses were carried out in the CJLSG1901 study to explore the efficacy and safety of pembrolizumab plus pemetrexed in older patients with metastatic non-squamous NSCLC, with a focus on the occurrence of pneumonitis (present vs. absent) after treatment initiation. The 95% confidence interval (CI) of the objective response rate (ORR) was estimated using Clopper-Pearson method. Survival functions were derived through the Kaplan-Meier method, and the median survival time, along with its 95% CIs, was calculated using the Brookmeyer-Crowley method.

Results: Of the 48 patients with metastatic non-squamous NSCLC included in the analysis, 9 (18.8%) developed pneumonitis, comprising 5 (10.4%) with Grade 1-2, and 4 (8.3%) with Grade 3. Patients in the pneumonitis group were predominantly male (88.9% vs. 74.4%). Postoperative recurrence was nearly twice as common in the pneumonitis group (44.4% vs. 20.5%). Patients with pneumonitis had a lower median number of treatment cycles (pemetrexed: 3.0 [range: 1-9] vs. 5.0 [range: 1-28]; pembrolizumab: 3.0 [range: 1-9] vs. 5.0 [range: 1-28]). The ORR was 44.4% (95% CI: 13.7-78.8) in the pneumonitis group and 35.9% (95% CI: 21.2-52.8) in the non-pneumonitis group. The median progression-free survival (PFS) was shorter in the pneumonitis group at 5.5 months [95% CI: 2.6-22.2] compared to 7.8 months [95% CI: 4.8-18.0] in the non-pneumonitis group. In contrast, the median overall survival (OS) was comparable between the groups (19.1 months [4.3-not calculated (NC)] vs. 21.2 months [16.3-NC]).

Conclusions: In conclusion, despite limited treatment exposure, patients who developed pneumonitis exhibited an ORR and OS comparable to those without pneumonitis. However, their PFS was shorter. Differences in patient backgrounds suggest that the risk of pneumonitis may be influenced by preexisting conditions and disease characteristics. This trial was registered at ClinicalTrials.gov (NCT04396457) and the Japan Registry of Clinical Trials (jRCTs041200012).

P1.11.12 Impact of Body Composition on Immunotherapy Response in Non-Small Cell Lung Cancer

X. Zheng
the First Affiliated Hospital of Guangzhou Medical University, guangzhou/CN

Introduction: Although body mass index (BMI) is a widely used prognostic indicator in non-small cell lung cancer (NSCLC), it fails to distinguish whether differences in immunotherapy response are driven by variations in muscle mass or adipose tissue. To address this limitation, we investigated the association between body composition parameters and clinical outcomes in NSCLC patients receiving immunotherapy.

Methods: This retrospective study involved 473 patients diagnosed with NSCLC between March 2023 and March 2025. Body composition was measured using bioelectrical impedance analysis at at treatment initation, assessing total body fat and muscle mass, as well as their distribution (normalized by height squared). Enrolled patients were followed for at least 6 months to assess clinical outcome. Cox proportional hazards regression models were employed to evaluate the relationship between body composition and progression-free survival (PFS). Logistic regression analysis was conducted to determine the association with the objective response rate (ORR). Additionally, joint effect analyses were performed to assess the combined impact of significant body composition parameters on clinical outcomes. Longitudinal changes in body composition during follow-up were also analyzed to assess their prognostic significance.

Results: A total of 125 patients (110 male [88%]; median age 60 years) were included. 19 body composition parameters were analyzed, among which skeletal muscle index (SMI) and visceral fat area (VFA) showed significant prognostic value. Multivariable Cox regression analysis, after adjusting for age, smoking history, BMI, clinical stage and histological type, demonstrated that a higher SMI (HR=0.42, 95% CI:0.18-0.96 , P=0.041) and a lower VFA (HR=3.32, 95% CI:1.55-7.10, P=0.002) were significantly associated with longer PFS. Additionally, logistic regression analysis indicated that higher SMI (OR=2.93, 95% CI: 1.05-8.18, P=0.041) and lower VFA (OR=0.25, 95% CI: 0.09-0.69, P=0.007) independently predicted the ORR. Joint effect analysis revealed that patients with high SMI but low VFA had an 87% lower risk of disease progression (HR=0.13, 95% CI:0.04-0.38, P<0.001) compared to those with low SMI but high VFA. Furthermore, a reduction in trunk fat mass exceeding 10% during follow-up was associated with poorer PFS (HR=3.54, 95% CI: 1.17-10.71, P=0.025).

Conclusions: Higher SMI and lower VFA were independently associated with improved PFS and better response to immunotherapy in NSCLC patients. These findings highlight that body composition assessment may offer superior prognostic value over BMI and help refine patient stratification for immunotherapy. Further studies are warranted to validate these findings and guide to enhance immunotherapy efficacy in NSCLC.

P1.11.13 A Phase II Study of Camrelizumab Plus Docetaxol in Advanced NCSLC Pre-Treated With Immune Checkpoint Inhibitors and Chemotherapy

J. Zhou[1], H. Xie[1], W. Yao[2], N. Li[3], X. Wang[4], H. Hu[4], D. Li[5], Y. Wei[1], Y. Zhu[1], Y. Wang[1], J. Tang[1], Y. Lui[1], J. Zou[1]
[1]Sichuan Clinical Research Center for Cancer, Sichuan Cancer Hospotal & Institute, Sichuan Cancer Center, University of Electronic Science and Technology of China, Chengdu/CN ,[2]Sichuan Clinical Research Center for Cancer, Sichuan Cancer Hospotal & Institute, Sichuan Cancer Center, University of Electronic Science and Technology of China, Cengdu/CN ,[3]Suining Central Hospital, Suining/CN ,[4]Sichuan Academy of Medical Sciences & Sichuan Provincial People's Hospital, Chengdu/CN ,[5]General Hospital of Western Theater Command, Chengdu/CN

Introduction: Rechallenge of immune checkpoint inhibitors (ICIs) plus chemotherapy has shown promise in treating advanced NCSLC after progression on standard first line treatment of ICI and chemotherapy combination therapy. This study focuses on assessing the efficacy and safety profile of camrelizumab and docetaxol combination therapy as a second-line in patients after progression on standard first line treatment of ICIs plus chemotherapy.

Methods: This study is a prospective multicenter phase II trial, advanced patients who experienced disease progression following first-line ICI and chemotherapy combination therapy. The regimen consisted of camrelizumab (200mg, IV, Q3W) and docetaxol (75mg/m2, IV, Q3w). The primary endpoint is progression-free survival (PFS). Secondary endpoints include overall survival (OS),objective response rate(ORR)and safety.

Results: As the date cut-off on March 31, 2025, this study included a cohort of 22 patients, all males. The median follow-up time was 11.6m, and the median PFS was 4.0m (95% CI:0.450-7.550). The median OS was not yet reached. The ORR was 11.8%, and the DCR was 75.5%. Reactive cutaneous capillary endothelial proliferation (RCCEP) was the characteristic adverse event associated with camrelizumab. Subgroup analysis indicated that the 13 patients who experience RCCEP derived more benefit from the treatment compared to the 9 patients without RCCEP (6.0m vs 1.9m,HR=0.358, 95% CI: 0.131-0.980,p value=0.046). Among the 16 patients with available PD-L1 TPS expression data, the five patients with PD-L1 TPS≥50% had a median PFS of 12.1m, while the eleven patients with PD-L1<50% had a median PFS of 1.9m (95% CI 1.597-2.203). No significant differences in outcomes were observed between patients with squamous cell carcinoma and those with non-squamous cell carcinoma, or between patients who achieved partial response (PR) versus stable disease (SD) from the front-line treatment.The most common treatment-related adverse effects (TRAEs) were fatigue (72.7%) and RCCEP (59.1%). The most frequent grader 3 or higher TRAEs were decreased white blood cells count (31.8%) and decreased of neutrophils count (31.8%).

Conclusions: Camrelizumab and docetaxol combination therapy may serve as a viable second-line treatment option for NCSLC patients who experience disease progression following front-line ICIs and chemotherapy combination treatment. Patients with PD-L1 TPS≥50% or those who develop RCCEP are more likely to benefit from this treatment. However, the small sample size is a limitation of this study, and further research with a larger cohort is needed to confirm those findings and achieve statistical significance.

P1.11.14 Depth of Response to Immunotherapy Is Associated With Survival Outcomes in Oligoprogressive NSCLC: A Real-World Data Analysis

K.C. Chua[1], Q. Huang[1], A. Hasan[1], S. Jin[1], S. Bates[1], A. Saadatpour[1], P. Szapary[1], D. Gomez[2]
[1]Johnson & Johnson, New Brunswick/NJ/USA ,[2]Memorial Sloan Kettering Cancer Center, New York/NY/USA

Introduction: Oligoprogressive disease (OPD) is recognized as a distinct clinical presentation with emerging data supporting the use of local ablative therapy (LAT=radiation/surgery) at sites of progression while continuing systemic therapy for non-progressing lesions (NPLs). Limited evidence exists regarding the outcomes of continuing immunotherapy (IO) in patients with OPD. In this real-world analysis, we aimed to investigate whether the "depth" of response (DepOR) to IO, defined as the change in sum of lesion diameters (SOD) across NPLs, correlates with survival outcomes. Characterizing the DepOR in NPLs may guide further disease management.

Methods: We utilized a longitudinal retrospective real-world dataset of patients with metastatic NSCLC without EGFR/ALK alterations receiving anti-PD-(L)1 across 10 US and European institutions. Lesion-level measurements were curated from routine CT scans. Patients with OPD during frontline IO treatment were identified as those with 1-5 extracranial progressing lesions (PLs) with no limit on NPLs. NPLs were longitudinally evaluated for response from the time of OPD until IO discontinuation. PLs were considered potential targets for LAT and were excluded in response evaluation. RECIST measurements were performed on NPLs to estimate the continued treatment effect attributable to IO post-OPD. Best response was determined as the maximum percent change in SOD across NPLs (excluding bone lesions). Time-to-next-treatment (TTNT) and overall survival (OS) were analyzed in patients grouped by varying DepOR.

Results: Among the 586 patients who received frontline IO (from December 2014 to November 2022), 215 (37%) developed OPD. Of these, 70 patients continued IO therapy and had ≥1 follow-up scan available. At the time of OPD, the median (interquartile range [IQR]) duration of frontline IO was 2.6 (2.2, 3.3) months; 55/70 (79%) patients had PLs in known metastatic sites, and 24/70 (34%) had PLs in new sites. The median (IQR) number of NPLs at the time of OPD was 4 (2-6). At the time of best response (median 3.4 months post-OPD), 32/70 (46%) patients experienced any SOD reduction in NPLs, including 11% (n=8/70) with ≥30% reduction. The remaining 38/70 (54%) patients had SOD increase or appearance of new lesion(s). Patients with any SOD reduction in NPLs had significantly improved OS and TTNT (Figure 1).

Conclusions: In this real-world cohort of patients receiving continued IO for oligoprogressive NSCLC, the depth of continued response in NPLs was associated with survival. This finding has clinical implications for monitoring DepOR in NPLs and optimizing interventions, particularly through novel IO combinations.

P1.11.15 PD-(L)1 Inhibitors for Treatment of Locally Advanced or Metastatic NSCLC in Asian and Non-Asian Patients: A Meta-Analysis

N. Girard[1], D. Cortinovis[2], G. Lopes[3], P.J. Voon[4], M. Austin Taylor[5], L. Zhan[5], S. Xu[6], K. Naicker[7], S. Peters[8]
[1]Institut Curie, Paris/FR ,[2]San Gerardo Hospital, Monza/IT ,[3]Sylvester Comprehensive Cancer Center at the University of Miami and the Miller School of Medicine, Florida/FL/USA ,[4]Sarawak General Hospital, Sarawak/MY ,[5]BeOne Medicines USA, Inc., Cambridge/MA/USA ,[6]BeOne Medicines (Shanghai) Co., Ltd., Shanghai/CN ,[7]BeOne Medicines (UK), London/GB ,[8]University of Lausanne and University Hospital of Vaud, Vaud/CH

Introduction: Non-small cell lung cancer (NSCLC) is the leading cause of cancer mortality worldwide, with higher death rates in Asia than in Europe and North America. Programmed cell death protein-(ligand) 1 (PD-[L]1) inhibitors are effective in NSCLC treatment, but their comparative effectiveness in Asian vs non-Asian populations is unclear.

Methods: A meta-analysis was conducted to assess the efficacy of PD-(L)1 inhibitor monotherapy or combination therapy (with platinum-based chemotherapy or cytotoxic T-lymphocyte-associated protein-4 [CTLA-4] inhibitors) in Asian and non-Asian patients with locally advanced or metastatic NSCLC, and to monitor safety and treatment patterns in the two cohorts using randomized controlled studies. Analyses were based on randomized controlled studies and by first- and second-line (1L, 2L/2L+) therapy. Overall survival (OS) and progression-free survival (PFS) hazard ratios (HRs) were extracted using random effects models. Safety outcomes were described if reported.

Results: Overall, 1431 records were screened, and 1L (n=21) and 2L/2L+ (n=10) studies that had enrolled a total of 10,233 patients with locally advanced or metastatic squamous/non-squamous NSCLC were identified. OS favoured 1L PD-(L)1 inhibitor monotherapy or combination therapy in both Asian (HR=0.70; 95% CI: 0.64, 0.76) and non-Asian (HR=0.71; 95% CI: 0.65, 0.77) patients (Table). Similar findings were observed with PFS in Asian (HR=0.53; 95% CI: 0.47, 0.59) and non-Asian (HR=0.58; 95% CI: 0.53, 0.64) patients. 1L PD-(L)1 inhibitor plus platinum-based chemotherapy and/or CTLA-4 inhibitors and 2L/2L+ PD-(L)1 inhibitor monotherapy were equally effective in Asian and non-Asian populations, but there was a greater magnitude of effect on PFS with 2L/2L+ PD-(L)1 inhibitor monotherapy in Asian (HR=0.57; 95% CI: 0.49, 0.67) than non-Asian (HR=0.73; 95% CI: 0.56, 0.95) patients; this may be related to differences in treatment patterns or prior surgery. Most studies showed low risk of bias using the Cochrane Risk of Bias 2 tool and rank-based Begg test. Safety data were obtained from eight 1L and two 2L/2L+ PD-(L)1 inhibitor studies. There was a higher incidence of treatment-related and immune-related adverse events (AEs) and discontinuations in some Asian populations. This may be linked to regional differences in AE resolution and differences in study periods.

Conclusions: These data demonstrate general consistency of outcomes with PD-(L)1 inhibitors for both Asian and non-Asian patients with 1L or 2L/2L+ locally advanced or metastatic NSCLC. More real-world evidence at the regional level will further confirm long-term clinical benefits and tolerability in specific patient populations.

Table. Survival Outcomes in Asian and Non-Asian Populations With Locally Advanced or Metastatic NSCLC

Outcome	Asian HR [95% CI]	Non-Asian HR [95% CI]	RE Model I^2 (*P* value)
Overall survival			
PD-(L)1 inhibitor 1L monotherapy or combination therapy	0.70 [0.64, 0.76]	0.71 [0.65, 0.77]	25% (.08)
PD-(L)1 inhibitor 1L combination therapy	0.70 [0.63, 0.76]	0.70 [0.62, 0.79]	32% (.06)
PD-(L)1 inhibitor 1L monotherapy or combination therapy (PD-L1 expression ≥50%)	0.50 [0.39, 0.64]	0.64 [0.55, 0.76]	0% (.53)
PD-(L)1 inhibitor as 2L/2L+ monotherapy or combination therapy	0.73 [0.64, 0.83]	0.71 [0.64, 0.78]	0% (.54)
Progression-free survival			
PD-(L)1 inhibitor 1L monotherapy or combination therapy	0.53 [0.47, 0.59]	0.58 [0.53, 0.64]	48% (.003)
PD-(L)1 inhibitor 1L combination therapy	0.53 [0.47, 0.60]	0.60 [0.53, 0.68]	55% (.001)
PD-(L)1 inhibitor 1L monotherapy or combination therapy (PD-L1 expression ≥50%)	0.38 [0.32, 0.44]	0.46 [0.37, 0.56]	4.6% (.40)
PD-(L)1 inhibitor as 2L/2L+ monotherapy or combination therapy	0.57 [0.49, 0.67]	0.73 [0.56, 0.95]	74% (.005)

Abbreviations: 1L, first-line; 2L/2L+, second-line/second-line-plus; CI, confidence interval; HR, hazard ratio; NSCLC, non-small cell lung cancer; PD-(L)1, programmed cell death protein-(ligand) 1; RE, random effects.

P1.11.16 Gut Microbiota: Associations Between Composition and Response to Immunotherapy in Non-Small Cell Lung Cancer

G.F. Moreira[1], I.B. Goncalves[1], G.F. Celestino[1], T.C. Montella[1], F.C. Dias[1], F.T.L. Taveira[1], C.A.C. Silva[2], C.G. Ferreira[1], A.C. Melo[1]
[1]Oncoclinicas, Rio de Janeiro/BR ,[2]Oncoclinicas, Salvador/BR

Introduction: Lung cancer (LC) is the leading cause ofcancer-related mortality worldwide. Immune checkpoint inhibitors (ICI) haverevolutionized cancer treatment, but surpass resistance is still a challenge. The gutmicrobiota (GM) impacts cancer immunosurveillance, and its composition has beenassociated with modulating immunotherapy efficacy. We conducted a prospectivestudy (NCT04965129) to evaluate the relationship between the GM and ICIresponse in patients with non-small cell lung cancer (NSCLC).

Methods: NSCLC patients eligible for ICI treatment, in stages III or IV, with ECOG performance status 0-2, and a life expectancy >16 weeks were included. Fecal samples were collected up to 20 days before immunotherapy initiation (T0). A pharmacist conducted monthly visits and weekly telemonitoring to assess drug interactions and provide pharmacotherapeutic follow-up for 16 weeks. The GM was analyzed by 16S rRNA sequencing. Treatment response was evaluated according to RECIST v1.0, considering disease control (DC) as complete response, partial response, or stable disease. Statistical analyses included Mann-Whitney non-parametric tests and Linear Discriminant Analysis (LDA) to identify significant differences in GM composition between ICI responders and non-responders.

Results: We included 27 patients from February 2022 to February 2024: mean age 70.6 years ± 7.5 [SD], predominantly male (59%), with two or more comorbidities (63%), and polypharmacy (74%). Most (85%) had PD-L1 <50, and 37% required pharmaceutical interventions. Around 60% of patients achieved disease control (DC). A total of 81 bacterial species differed significantly between PD and DC ($p<0.05$) groups. No records were identified in the literature relating the interface between GM and ICI response for 74 of these species (91%). In the DC group, an enrichment with health-related Lachnospiraceae (Roseburia spp., Blautia spp.) and Alistipes spp. was observed. All patients with DC were positive for Akkermansia muciniphila versus 33% in PD patients, associating a protective role of these microorganisms in immunotherapy response. Conversely, the genera Acidaminobacter and Anaerovorax predominated (3.78 and 3.38-fold, respectively) in PD patients, related to greater ICI resistance. Analysis of the Poribacteria phylum showed a significant difference between the two types of treatment response ($p = 0.031$), being found in 46% of DC patients and only 8% in PD. Furthermore, Acidaminococcus fermentans was identified in 37.5% of patients in the DC group ($p = 0.0124$) but was absent in all PD participants. Bacteroides caccae ($p = 0.035$) and Prevotella copri ($p = 0.045$) were present in all patients in the study.

Conclusions: GM composition modulates the response to immunotherapy in NSCLC. Our study is pioneering in the evaluation of Brazilian LC patients treated with ICIs. We contribute to the knowledge about the GM and its relevance for precision medicine, aiming for more robust and inclusive biomarkers.

Città della Salute e della Scienza di Torino, Ospedale Molinette, Turin/IT

Introduction: Monoclonal antibodies (mAbs) targeting PD-(L)1 improve survival across most NSCLC stages, but resistance—either primary or acquired—remains common. Recent trials have explored PD-(L)1-based re-challenge strategies in advanced NSCLC, often in combination with other agents including other immunotherapies, tyrosine kinase inhibitors (TKIs) and VEGF mAbs, with mixed results.

Methods: The literature search on MEDLINE and EMBASE was performed in January 2025 independently by two groups of authors and eligible studies retrieved by either one or both groups were included. Randomised and non-randomised trials evaluating the safety and efficacy of second or further line of re-treatment with anti-PD-(L)1 mAbs in patients with advanced NSCLC who have previously received the same class of agents and platinum chemotherapy were included. All analyses were performed with RevMan.

Results: Two groups of authors independently identified 2957 and 5830 items, respectively. After removal of duplicates and merging of eligible studies resulting from each iteration of the search strategy, 9 randomised clinical trials were included (NCT03656094, CONTACT-01, KEYVIBE-002, LEAP-008, Lung-MAP S1800A, Lung-MAP S1800D, Morpheus Lung, SAFFRON-301, SAPPHIRE). Experimental treatment consisted of anti-PD-(L)1 combined with chemotherapy (n=2), anti-VEGF mAbs (n=2), tyrosine kinase inhibitors (n=4) and ICIs/immunostimulatory agents (n=2). The control arm consisted of docetaxel (n=6) and investigator's choice SoC chemotherapy (n=3). Most of the included trials enrolled patients independently of the pattern of resistance to anti-PD(L)1 mAbs. Among 1120 and 1123 patients treated with either anti-PD-(L)1-based combinations or SoC, OS was not significantly improved with anti-PD-(L)1-based combinations (hazard ratio (HR) 0.90, 95%CI 0.81-1.01, I2 0%, Figure 1). Similarly, progression-free survival was not significantly improved with anti-PD-(L)1-based combinations (HR 0.92, 95%CI 0.84-1.02, I2 45%) and overall response rate was similar (odds ratio 1.09, 95%CI 0.87-1.36, I2 23%). Additionally, 99 reports from non-randomised clinical trials were identified and further efficacy and safety analyses are ongoing.

Conclusions: Re-challenge with anti-PD-(L)1-based combinations in pre-treated patients did not demonstrate significant improvements in OS and PFS compared to SoC, an outcome that, despite strong biological rationale, remains unexpectedly disappointing. Nonetheless, further investigation is warranted with a focus on refined patient selection and deeper mechanistic understanding.

P1.11.18 Real-World Characterization of Response Kinetics in Patients With Metastatic NSCLC Receiving First-Line Immunotherapy

M.E. Marmarelis[1], K.C. Chua[2], A. Hasan[2], J. Da Silva[2], S. Bates[2], A. Saadatpour[2], Q. Huang[2]
[1]University of Pennsylvania, Philadelphia/PA/USA ,[2]Johnson & Johnson, New Brunswick/NJ/USA

Introduction: Anti-PD-(L)1 is a preferred first-line (1L) treatment for metastatic non-small cell lung cancer (mNSCLC) without driver mutations; however, many patients have inadequate response and experience disease progression. Understanding tumor response dynamics during immunotherapy is critical to identify optimal timing for combination interventions aimed to augment response to anti-PD-(L)1 and improve survival. Here, we characterized the response kinetics of 1L anti-PD-(L)1 in a real-world cohort of patients with mNSCLC and investigated the association of depth of response (DepOR) at 3 months with survival.

Methods: This study utilized a retrospective real-world dataset of patients with mNSCLC undergoing anti-PD-(L)1-based treatment across 10 US and European institutions including radiologist-assessed imaging data. Response was assessed per RECIST v1.1 on routine CT scans. The agreement between 3-month response and best response was assessed using cross-tabulation. The DepOR at 3 months after anti-PD-(L)1 initiation was measured as percent change in the sum of longest diameters (SLD) from baseline. Real-world progression-free survival (rwPFS) and overall survival (OS) were evaluated in patients grouped by varying degree of 3-month DepOR.

Results: A total of 414 patients were identified with evaluable RECIST assessments at both baseline and 3 months after anti-PD-(L)1 initiation. The median (min, max) number of scans per patient in the cohort was 3 (2, 10). Majority of patients achieved best response at 3 months. Deepening of response after 3 months was observed in only 8% of patients. Patients were classified into subgroups based on their 3-month DepOR: 75-100% SLD reduction (SLD-R), 50-<75% SLD-R, 30-<50% SLD-R, 0-<30% SLD-R, SLD increase, and progressive disease. Proportion of patients in each subgroup was 5%, 13%, 25%, 30%, 10% and 18%, respectively. Similar distributions of 3-month DepOR were observed in patients receiving anti-PD-(L)1 monotherapy vs. anti-PD-(L)1/platinum combination therapy. All patient subgroups experiencing SLD reduction at 3-month exhibited significantly improved rwPFS and OS when compared to those with no tumor shrinkage or progression at 3 months (Figure 1). Patients with 50-100% SLD-R had significantly improved rwPFS (p=0.023) and a trend toward better OS (p=0.059) than patients with suboptimal response (0-<50% SLD-R).

Conclusions: This study highlights that patients exhibiting sub-optimal response can be identified early in their treatment trajectory based on 3-month DepOR. Furthermore, if a significant reduction in tumor burden is not achieved at 3 months, it is highly unlikely that further tumor shrinkage will occur. Our findings may inform patient selection for intensification strategies based on the tumor response at 3 months.

P1.11.19 Real-World Outcomes of Nivolumab Plus Ipilimumab in Elderly NSCLC Patients (=75): A Retrospective Analysis

S. Minami, Y. Yamazaki, T. Doman, A. Narumi, Y. Toi, Y. Kimura, S. Sugawara
Sendai Kousei Hospital, Sendai city/JP

Introduction: Immune checkpoint inhibitors (ICIs) have revolutionized the treatment of non-small cell lung cancer (NSCLC), offering durable responses. However, elderly patients (≥75years) are underrepresented in clinical trials due to age-related comorbidities and functional decline. Although the combination of nivolumab and ipilimumab has become a standard first-line option based on trials like CheckMate 227, data on its efficacy and safety in elderly populations remain limited.

Methods: We conducted a single-center retrospective observational study to evaluate the clinical outcomes of nivolumab plus ipilimumab in elderly patients with advanced NSCLC lacking driver mutations. Twenty-seven patients aged ≥75 years who received this regimen between February 2021 and October 2023 were included. Clinical data were obtained from electronic medical records. Primary endpoints were progression-free survival (PFS) and overall survival (OS), while secondary endpoints included objective response rate (ORR), disease control rate (DCR), and immune-related adverse events (irAEs). Risk factors associated with progressive disease (PD) as best response were explored using logistic regression, and multivariate analysis was performed with a Cox proportional hazards model.

Results: The median age was 80 years (range 75-90), and 66.7% were male. PD-L1 expression was positive in 8 (29.6%), negative in 18 (66.7%), and unknown in 1 (3.7%). Median PFS was 6.5 months (95% CI: 2.6-13.6), and OS was 13.0 months (95% CI: 4.4-32.7). ORR was 22.2% (6 partial responses), and DCR was 62.9% (11 stable diseases). PD occurred in 10 patients (37.1%). Logistic regression analysis identified never-smoking status as significantly associated with a lower risk of PD (OR = 0.12, 95% CI: 0.01-0.98, p = 0.048), while non-squamous histology showed a trend toward reduced PD risk (OR = 0.17, 95% CI: 0.03-1.09, p = 0.061). The presence of brain metastases significantly increased the likelihood of PD (OR = 24.0, 95% CI: 2.23-260.0, p = 0.009). In multivariate Cox regression analysis, brain metastases remained a significant factor for disease progression (HR = 24.00, 95% CI: 2.21-260.00, p = 0.009). Regarding irAEs, 18 patients (66.7%) experienced any grade, and 11 (40.7%) had grade ≥3 events. Skin rash (n=8), lung injury (n=4), and colitis (n=4) were the most frequent. Grade ≥3 events included lung injury (n=4), arthritis (n=1), adrenal insufficiency (n=1), kidney injury (n=2). One treatment-related death occurred due to pneumonitis.

Conclusions: Nivolumab plus ipilimumab appears to be a feasible treatment for elderly patients with advanced NSCLC, providing meaningful disease control. However, patients with brain metastases may have significantly poorer outcomes.

P1.11.20 Camrelizumab-Based Therapy-Induced RCCEP in Advanced NSCLC Patients: A Pooled Analysis of Two Phase III Registration Trials

C. Zhou[1], Z. Hou[2], C. Ma[2], Y. Chen[2], S. Liu[2]
[1]Shanghai East Hospital, Shanghai/CN ,[2]Jiangsu Hengrui Pharmaceuticals Co., Ltd., Lianyungang/CN

Introduction: Cutaneous immune-related adverse events (irAEs), the most common toxicities of immune checkpoint inhibitors (ICIs), have been reported to positively associate with favorable survival outcomes in ICIs-treated patients with advanced cancer. Reactive cutaneous capillary endothelial proliferation (RCCEP), a distinctive irAE uniquely observed with camrelizumab (PD-1 antibody), may correlate with patient prognosis as well. This pooled analysis aimed to elucidate the clinical features of RCCEP and explore its prognostic relevance in advanced non-small cell lung cancer (NSCLC) patients.

Methods: Individual patient-level data in this pooled analysis were derived from two phase III registration trials, CameL (NCT03134872) and CameL-sq (NCT03668496). The CameL study enrolled patients with stage IIIB-IV non-squamous NSCLC without EGFR or ALK alterations, treated with camrelizumab combined with chemotherapy comprising pemetrexed and carboplatin. The CameL-sq study included patients with stage IIIB-IV squamous NSCLC receiving camrelizumab plus chemotherapy consisting of paclitaxel and carboplatin. Landmark analyses were performed to assess survival outcomes, taking the median time to first RCCEP onset as the time zero-point reference.

Results: RCCEP occurred in 73.4% (292/398) of patients, with a median age of 60.0 years (IQR: 54.0-65.0), the predominance of males (77.4%) and ECOG performance statuses of 0 (25.7%) or 1 (74.3%). The severity of RCCEP was primarily grade 1 (59.3%) and grade 2 (12.6%), with grade ≥3 events accounting for merely 1.5%. Treatment discontinuation due to RCCEP was rare, occurring in only 0.5% (2/398) of patients. The median frequency of RCCEP events was 1.0 (IQR: 1.0-2.0). The median time to first RCCEP onset was 1.48 months (IQR: 0.95-2.27); thus, a 2-month landmark analysis of survival was conducted. Compared with patients who did not develop RCCEP, those who did exhibited longer duration of camrelizumab exposure and increased cumulative exposure to camrelizumab, along with superior clinical outcomes including higher objective response rates (ORR: 71.9% vs. 36.8%), prolonged median progression-free survival (mPFS) [landmark analysis] (13.01 vs. 6.97 months; HR=0.43; 95% CI: 0.31-0.60), and extended median overall survival (mOS) [landmark analysis] (31.70 vs. 12.22 months; HR=0.30; 95% CI: 0.22-0.41).

Conclusions: This pooled analysis confirmed that RCCEP was relatively prevalent yet predominantly mild in severity among advanced NSCLC patients treated with camrelizumab-based regimens. Notably, the emergence of RCCEP positively correlated with enhanced efficacy, evidenced by improved ORR, prolonged PFS and OS, underscoring RCCEP as a potential predictive biomarker for therapeutic efficacy.

P1.11.21 Target Lesion Necrosis Percentage as a Predictor for Response to Immune Checkpoint Inhibitors in NSCLC: A Retrospective Analysis

A. Narula[1], P.K. Singh[2], G. Arya[3], T. Narula[4], K. Chugh[3], A. Ahuja[3]
[1]Narula Diagnostic Centre & Institute, Rohtak/IN ,[2]Pandit Bhgwat Dayal Sharma Post Graduate Institute of Medical Sciences, Rohtak, Rohtak/IN ,[3]Pandit Bhagwat Dayal Sharma Post Graduate Institute of Medical Sciences, Rohtak/IN ,[4]Narula Diagnostic Centre, Rohtak/IN

Introduction: Tumor-necrosis is a common finding in computed tomography (CT) scans of non-small-cell-lung cancer (NSCLC) patients and is associated with high tumor grade and poor prognosis. It is hypothesized that high necrosis proportion can indicate inflamed tumor microenvironment which can favor use of immune checkpoint inhibitors.

Methods: This was a retrospective single center study on NSCLC patients (stage IIIB or higher) who progressed/relapsed after first-line therapy and received single-agent Nivolumab. Anonymized contrast-enhanced CT scans done at baseline visit (before starting nivolumab) were used for analysis. Response was classified as per RECIST1.1 criteria and the radiologist (AN) who analyzed the CT scans was unaware of the same. The axial section on CT cuts exhibiting the maximal tumoral cross-sectional area was selected. Tumoral area and necrotic area (both discrete and scattered) were recorded. Necrotic-area was defined based on cut off of hounsfield units less than 50(figure1). Percentage-necrotic-area was compared among responders and non-responders.

Results: 48 subjects with complete follow up data were identified. Majority were males (91.7%), had an ECOG-PS of 1(89.6%), and were stage IV (70.8%). Most common histology was squamous-cell (75%) and adenocarcinoma were 10.4%. Mean age was 60.29±8.6 years and mean necrotic area percentage was 24.75±15.9%. 66.7% (32) patients had disease control of which 75% (24) achieved partial remission (as best response). Percentage-necrosis-area was significantly higher in the responders group [32.92±11.5 versus 16.6±15.7; t(46):4.1; p<0.001; Cohen's D: 13.8] as well as disease control group [9.28±6.2 versus 32.5±13.4; t(46):-6.6; p<0.001; Cohen's D: 11.6] compared to non-responders (stable-disease and progressive-disease combined) and progressive-disease groups, respectively. ROC-AUC for predicting progression was 0.941 with best diagnostic accuracy at 23.18% necrotic-area. ROC-ROC for response prediction was 0.823(figure2).

Conclusions: Measuring necrosis-percentage-area can be used to anticipate response to nivolumab in second line setting. Larger prospective studies are required to confirm our preliminary findings.

P1.11.22 Extracellular Vesicle-Derived LncRNA Signatures in Serum for Diagnosis and Prognosis of Checkpoint Inhibitor-Related Pneumonitis

Y. Yang[1], H. Deng[1,2], F. Wang[1], C. Zhou[1], L. Wang[2], X. Lin[1]
[1]The First Affiliated Hospital of Guangzhou Medical University, National Center for Respiratory Medicine, National Clinical Research Center for Respiratory Disease, State Key Laboratory of Respiratory Disease, Guangzhou Institute of Respiratory Health, Guangzhou/CN ,[2]Guangzhou Key Laboratory for Clinical Rapid Diagnosis and Early Warning of Infectious Diseases, KingMed School of Laboratory Medicine, Guangzhou Medical University, Guangzhou/CN

Introduction: Checkpoint inhibitor-related pneumonitis (CIP) is a life-threatening immune-related adverse event (irAE) associated with immune checkpoint inhibitors. Due to the absence of specific diagnostic tools, CIP is frequently misdiagnosed or underdiagnosed in clinical practice. This highlights the urgent need for more accurate and non-invasive diagnostic approaches. In this study, we investigate the potential of serum extracellular vesicle (EV)-derived lncRNAs as novel biomarkers for the diagnosis and prognosis of CIP.

Methods: Serum EV lncRNAs from three patient groups—CIP (patients treated with PD-1/PD-L1 inhibitor and with CIP), ICI (patients treated with PD-1/PD-L1 inhibitor and without CIP), and PNE (infectious pneumonia)—were detected via lncRNA sequencing, with selected lncRNAs validated by qRT-PCR in a training cohort (n = 103). The diagnostic (CIP vs. ICI) and differential diagnostic (CIP vs. PNE) models were constructed and assessed for diagnostic performance with Receiver Operating Characteristic (ROC) curves. The results were further validated in an independent validation cohort (n = 74). LASSO regression identified key peripheral blood parameters for comparison and integration with EV-lncRNA models to enhance diagnostic accuracy. Clinical applicability was evaluated via DCA. A prognostic model based on the CIP diagnostic signature was constructed using Cox regression to stratify patients by overall survival (OS) after CIP onset.

Results: Two lncRNAs (TTC9-DT and ITGA2-AS1) were significantly elevated in the CIP group compared to the ICI group and were confirmed as key biomarkers for CIP diagnosis, with TTC9-DT also distinguishing CIP from PNE. In CIP diagnosis (CIP vs. ICI), the CILnc model (TTC9-DT + ITGA2-AS1) achieved high diagnostic accuracy in the training cohort (AUC = 0.945, 95% CI [0.883-1.000]) and was validated in the independent cohort (AUC = 0.983, 95% CI [0.941-1.000]). For differentiating CIP from PNE (CIP vs. PNE), TTC9-DT yielded an AUC of 0.704 (95% CI [0.551-0.857]) in the training cohort and 0.860 (95% CI [0.712-1.000]) in the validation cohort. Through LASSO regression, absolute neutrophil count (NEU), absolute lymphocyte count (LYM), and lactate dehydrogenase (LDH) were identified from routine peripheral blood markers, but their diagnostic efficacy was worse than lncRNA-based models. When combined with specific blood markers, diagnostic performance improved further. The efficacy of CILnc+NEU model was validated for CIP diagnosis (CIP vs. ICI) with AUCs of 0.948 (95% CI [0.887-1.000]) (training cohort) and 0.991 (95% CI [0.965-1.000]) (validation cohort). TTC9-DT+LYM+LDH effectively distinguished CIP from PNE with AUCs of 0.827 (95% CI [0.716-0.939]) and 1.000 (95% CI [1.000-1.000]). Both models demonstrated strong clinical utility, as confirmed by DCA. Additionally, the CILnc+NEU signature effectively stratified CIP patients based on OS after CIP onset (hazard ratio = 12.618, 95% CI [2.766-57.566]).

Conclusions: Serum EV lncRNA-based signatures (CILnc+NEU and TTC9-DT+LYM+LDH) offer specific, non-invasive tools for diagnosing CIP, and they are also potential prognostic markers for CIP patients. These findings may help to promote precise clinical diagnosis and individualized management of CIP.

P1.11.23 Co-Culturing LCOs and Lymphocytes Derived From Pleural Effusion Potentially Implement Personalized Immunotherapy

X-H. Guan[1], Z-X. Chen[2], X-C. Lin[1], Y-H. Yao[3], H-J. Chen[1], H. Sun[1], J-J. Yang[1]
[1]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Guangzhou/CN ,[2]Guangdong Research Center of Organoid Engineering and Technology, Guangzhou/CN ,[3]Department of Oncology, Shenzhen People's Hospital, Shenzhen/CN

Introduction: Identifying lung cancer patients who will respond to immunotherapy remains a significant challenge. Organoid-lymphocyte co-culture represents a potentially valuable tool for improving patient selection. The aim of this study is to establish a co-culture system of human derived lung cancer organoids and lymphocytes derived from pleural effusion, and correlate the results of drug sensitivity testing with real-world clinical efficacy in patients.

Methods: Between October 31, 2021, and May 31, 2024, a total of 328 specimens were collected from 204 patients diagnosed with advanced lung cancer for organoid culture. Co-culture systems were established using lymphocytes and tumor cells isolated from malignant pleural effusions. The ATP bioluminescence tumor chemosensitivity assay (ATP-TCA) was applied to measure changes in cell viability. The expression levels of anti-tumor immune factors in the co-culture system were quantified using the Olink proteomics assay, both before and after treatment. Flow cytometric analysis was also performed to characterize the anti-tumor immune function of T cells.

Results: Compared to malignant pleural effusion lymphocytes (MPELs), we observed a significantly higher proportion of CD11b+ cells within the PBMCs (P<0.001). which may indicate that MPELs is more suitable for constructing organoid lymphocyte co-culture systems than PBMCs. Guided by the above results, a co-culture system of lung cancer organoids (LCOs) and pleural effusion-derived lymphocytes was established. Further, Olink proteomics analysis revealed that pembrolizumab treatment in a co-culture system significantly increased the expression of CD28, IL-12, TNF, PD-L2, and NCR1 (P<0.01). Conversely, the expression of IL-13, IL-5, PD-1, CXCL1, and PTN was significantly decreased (P<0.01). In a separate co-culture system treated with pembrolizumab, a significant increase was observed solely in IL-13 expression. This outcome aligns with the drug sensitivity assay results for this system, which indicated that pembrolizumab was ineffective. Flow cytometry analysis of marking CD8+, CD137+, and CD107a+ T cell showed that compared to peripheral blood, the LCOs pleural lymphocytes co-culture system more accurately reflected the anti-tumor efficacy of T cells. Overall, the analysis showed that the success rate of establishing co-culture system in our study was 29.8% (98/328). The chi-square analysis revealed a statistically significant association between the type of sample taken and the success of establishment (P=0.025). By analysed, the diagnostic threshold (minimum requirement for cell viability reduction) for drug efficacy is 31.93%. ROC analysis showed that the area under the curve (AUC) value was 0.765 (P=0.009). Based on this criterion, under the co-culture system of LCOs and lymphocytes derived from pleural fluid, the consistency between drug sensitivity and clinical efficacy was 78.6% (11/14) and 70.0% (14/20) in the immunotherapy and targeted therapy/chemotherapy groups respectively. The total consistency was 73.5% (25/34), but 37.5% (3/8) under the co-culture system of LCOs and lymphocytes from peripheral blood.

Conclusions: For the first time, we have established a co-culture system of lung cancer organoids (LCOs) and autologous lymphocytes derived from pleural effusion. Notably, drug sensitivity testing in this system demonstrates high concordance with observed clinical efficacy.

Introduction: Despite the unprecedented long lasting-responses observed with immunotherapy (IT) in non-small cell lung cancer (NSCLC), a considerable proportion of patients does not respond to upfront IT-based strategies. Primary resistance to first-line chemo-immunotherapy (CT-IT) still represents an unmet clinical need and an underexplored phenomenon.

Methods: This multicenter retrospective-prospective study included patients diagnosed with advanced lung adenocarcinoma (LUAD) who received first-line CT-IT (cis/carboplatin, pemetrexed, and pembrolizumab) starting from September 4th, 2018, across 33 Italian Centers. This analysis aimed to describe the real-world clinicopathological features and outcomes of patients with primary resistance to CT-IT, defined as RECIST progression (PD) within ≤6 months from treatment initiation and to compare them with those who had a follow-up exceeding 6 months. Both groups had a minimum treatment exposure of 6 weeks as per Society for Immunotherapy of Cancer (SITC) guidelines.

Results: A total of 1068 patients were enrolled by the data cut-off (January 31st, 2023), and 768 of these were included in this analysis. Among the 225 (29.3%) patients who were primary resistant to CT-IT, the median age was 65 years (range, 32-82), 141 (62.7%) patients were male, and 190 (86.4%) were current/former smokers. At univariate analysis, compared with the rest of the study population (n=543), patients with primary resistance had a poorer ECOG PS (ECOG PS ≥2: 9.9% vs 4.5%, p=0.003), a higher percentage of pre-treatment bone metastasis (48.9% vs 31.7%, p<0.001), liver metastasis (15.6% vs 10.3%, p=0.041) and were more likely to have more than three metastatic sites (54.2% vs 37.6%, p<0.001). The most common best response to CT-IT in patients with primary resistance was progressive disease (PD) in 113 (50.4%) cases, compared to a partial response in 338 (62.2%) of the remaining patients (p<0.001). Among patients with primary resistance, those whose best response to CT-IT was PD exhibited even worse baseline clinical features (ECOG PS ≥2: 13.3%, liver metastasis: 16.8%, >three metastatic sites: 59.3%). At the time of PD, a higher proportion of patients with primary resistance continued CT-IT beyond PD (24.0% vs 13.0%, p<0.001). Median duration of treatment (DoT) and median overall survival (OS) were significantly decreased in patients with primary resistance compared to the counterpart (mDoT: 3.8 vs 11.1 months, p<0.001; mOS: 8.3 vs 35.6 months, p<0.001). Furthermore, patients with primary resistance less frequently received a second-line treatment (56.0% vs 66.5%, p=0.005), which consisted of docetaxel in 39 (31.0%) patients and docetaxel plus nintedanib in 31 (24.6%) patients. Of note, patients with primary resistance more frequently achieved progression of disease as best response to second-line therapy (46.0% vs 35.0%, p=0.015).

Conclusions: Baseline characteristics such as ECOG PS ≥2, the presence of bone and liver metastasis and having more than three metastatic sites were significantly more prevalent in LUAD patients with primary resistance to first-line CT-IT. These patients also exhibited a higher likelihood of experiencing PD as the best response to both first-line and second-line therapy, suggesting that special caution should be exercised when treating patients with these unfavorable features.

P1.11.25 Genomic Characterticers, Survival and Prognostic Analysis of Advanced NSCLC With Kirsten Rat Sarcoma Mutations With Brain Metastases

Y. Chen, Y. Fan
Zhejiang Cancer Hospital, Hangzhou/CN

Introduction: The brain is a common site of metastasis for lung cancer, however, data on the incidence of brain metastasis, genetic landscape and survival prognosis analysis in patients with KRAS-mutant is limited. Therefore, we conducted this single-center retrospective study to characterize the incidence of brain metastasis in KRAS-mutated patients and to analyze the prognostic factors related to their survival.

Methods: A total of 2,429 patients with advanced non-small cell lung cancer (NSCLC) who were hospitalized at Zhejiang Cancer Hospital from January 2017 to June 2023 were screened. The primary endpoint of the study was the overall survival (OS) . OS was defined as the time from the diagnosis of brain metastasis to the last follow-up or death. Kaplan-Meier methods were used to generate survival curves, and the log-rank test was employed to assess differences. Cox proportional hazards regression was used to evaluate prognostic factors associated with OS.

Results: In analsysis,217 patients with KRAS-mutant were identified, of whom 63 had brain metastasis. The incidence of brain metastasis at diagnosis was 35/217 (16.1%), and the overall incidence of brain metastasis was 63/217 (29.0%). Among the KRAS subtypes, the incidence of brain metastasis for G12C, G12D, G12V, and G12A was 33.9% (20/59), 19.4% (6/31), 28.6% (6/21), and 40.0% (6/15), respectively. The follow-up cut-off date was December 10, 2024, the median OS of 217 patients with KRAS- mutant was 19.4 months (95% CI: 16.9-24.3 months). The median OS of 63 patients with brain metastasis was 15.2 months (95% CI: 13.2-22.1 months), and patients with brain metastasis had significantly shorter median OS compared to those without brain metastasis (15.2 vs. 22.2 months, p = 0.038). There was no significant difference in OS between BM patients with KRAS G12C and those with other subtypes (16.9 vs. 14.9 months, p = 0.27). During the treatment after brain metastasis, 47 patients had received chemotherapy with immunotherapy, 13 patients had received chemotherapy with anti-angiogenic therapy, and 3 patients had only received TKI treatment in clinical research. Those who had received chemotherapy with immunotherapy had longer OS compared to those who did not (16.3 vs. 6.95 months, p = 0.029). Patients who received brain radiotherapy had a tendency towards longer survival compared with those who did not, although the difference was not statistically significant (17.7 vs. 12.5 months, p = 0.15). Univariate and multivariate analysis revealed that the combination of chemotherapy and immunotherapy is an independent prognostic factor.

Conclusions: The incidence of brain metastasis in patients with KRAS-mutant is relatively low. Patients with brain metastasis have a poorer prognosis than those without brain metastasis. Immunotherapy after brain metastasis can improve the overall survival (OS), Univariate and multivariate analysis revealed that the combination of chemotherapy and immunotherapy could improve those patients' prognosis.

P1.11.26 Temporal Optimization of Radiotherapy-Immunotherapy Synergy for NSCLC Brain Oligo-Metastases: Prospective Assessment of Prognosis Outcomes

X. Gong
Shanghai pulmonary hospital, Shanghai/CN

Introduction: Initiating immunotherapy within a specific time window (7-14 days) after radiotherapy may maximize the synergistic effect between antigen release and T-cell activation. This prospective study investigates the optimal sequencing of stereotactic radiotherapy (SRT) combined with immune checkpoint inhibitors (ICIs) in patients with NSCLC brain oligo-metastases, assessing differential clinical responses based on treatment timing.

Methods: From 2018 to 2023, this study enrolled the NSCLC patients with 1-3 BMs who received SRT combined with ICIs. After initial diagnosis of brain metastases, patients first underwent SRT followed by concurrent (interval ≤14 days) or sequential (interval >14 days) ICIs treatment. Based on the temporal interval between the two therapies, patients were followed up, and differences in survival outcomes, intracranial response, and safety profiles were compared between the two cohorts.

Results: Ultimately, this study enrolled 65 patients, including 38 in the concurrent treatment group and 27 in the sequential treatment group. Compared to sequential therapy, concurrent treatment significantly improved overall survival (median OS: 39.5 vs. 16.5 months, hazard ratio [HR]: 0.44, 95% confidence interval [CI]: 0.22-0.85, p = 0.012) and progression-free survival (median PFS: 9.2 vs. 6.5 months, HR: 0.52, 95% CI: 0.31-0.88, p = 0.014). Notably, in patients with PD-L1-positive expression or those with a single brain metastasis, concurrent therapy demonstrated a significant increase in intracranial progression-free survival (median iPFS: 11.0 vs. 9.1 months, HR: 0.41, 95% CI: 0.18-0.98), p = 0.037; 16.7 vs. 9.7 months, HR: 0.61, 95% CI: 0.26-0.99, p = 0.046) compared to sequential treatment. Based on lesion-level assessment of intracranial treatment response, concurrent therapy significantly enhanced the intracranial objective response rate (iORR: 72.7% vs. 51.4%, p = 0.036). No significant differences in treatment-related toxicities were observed between the two groups.

Conclusions: Concurrent SRT and ICIs therapy (interval ≤14 days) significantly improved prognosis outcomes compared to sequential treatment in NSCLC patients with oligo-brain metastases, without increasing treatment-related toxicities. These findings underscore the critical role of initiating immunotherapy a post-radiotherapy window within 14 days to optimize synergistic efficacy, supporting concurrent administration as a preferred strategy for this patient population.

P1.11.27 Optimal Immunotherapy Regimen for STK11 or KEAP1 Mutant Metastatic Non-Small Cell Lung Cancer

N. Shammas[1], S. Bhatti[2]
[1]CHI St. Vincent, Hot Springs/AR/USA ,[2]University of Arkansas for Medical Sciences, Little Rock/AR/USA

Introduction: Immunotherapy-based regimens have significantly improved outcomes for patients with metastatic non-small cell lung cancer (mNSCLC). However, immunotherapy benefits may be limited in specific subsets of patients with cancers harboring mutations in serine/threonine 11 (STK11) and Kelch-like ECH-associated protein 1 (KEAP1). The optimal immunotherapy strategy for these patients is unknown.

Methods: We reviewed randomized control trials that led to regulatory approval of immunotherapy-based regimens in mNSCLC by the FDA. During our analysis, we only included trials that reported outcomes for STK11 and KEAP1 patients. Since information on STK11/KEAP1 co-mutants was limited, we did not include this information in our analysis. In trials where multiple experimental treatments were tested, we included data on all arms, even if a particular experimental arm did not lead to regulatory approval. We retrieved data regarding outcomes, including overall response rates (ORR), median progression-free survival (mPFS), and overall survival (mOS) for experimental and control arms.

Results: We included 7 randomized trials in our analysis. Keynote 42 was the only included trial evaluating single-agent immunotherapy pembrolizumab in the PDL1-positive population. KEAP1 and STK11 patients had improved ORR and OS with pembrolizumab, but the PFS was not improved. Keynote 189 evaluated chemotherapy plus pembrolizumab and showed improvement in PFS, OS and ORR in the experimental arm. However, combination chemoimmunotherapy with PDL1 antibodies durvalumab and atezolizumab in POSEIDON and IMPOWER 150 underperformed when compared to standard chemotherapy in both KEAP1 and STK11, limiting their role for these patients. Anti-CTLA4 addition to Anti-PD(L)1 improved outcomes in POSEIDON, checkmate 227 and checkmate 9LA trials supporting combination checkpoint blockade, which may abrogate the deleterious effect of STK11 and KEAP1. Lastly, a four-drug regimen of chemotherapy plus bevacizumab and atezolizumab (ABCP) from IMPOWER 150 did not appear to benefit STK11 patients, but KEAP 1 patients did derive benefit.

Conclusions: Though STK11 and KEAP1 mutations in NSCLC are associated with a poor prognosis, these patients can still benefit from immunotherapy-based regimens over chemotherapy alone. We conclude that these patients should receive combination treatments such as pembrolizumab plus chemotherapy or dual checkpoint blockade with or without chemotherapy. Anti-PDL1 antibodies should not be considered interchangeable with pembrolizumab in this patient population. Patients not candidates for combination due to frailty or medical comorbidities may still derive benefit from single agent pembrolizumab if PDL1 is positive.

IO regimen type	Trial	Experimental (E) arm	Control (C) Arm	No. of analyzed STK11 pts (N)	mPFS in STK11 – E vs C arm, HR (CI)	mOS in STK11– E vs C arm, HR (CI)	ORR in STK11 – E vs C arm (%)	No of KEAP1 patients across arms (N)	PFS in KEAP1 - E vs C arm, HR (CI)	OS in KEAP1 E vs C , HR (CI)	ORR in KEAP1 – E vs C arm (%)

P1.11.28 Nomogram and Effectiveness of Bone-Modifying Agents in Advanced Driver-Negative NSCLC: A Retrospective Real-World Study

L. Zhang[1], X. Dong[1], Z. Han[2], J. Chen[3], Y. Liang[4], L. Man[5], X. Qu[1], Y. Liu[1]
[1]The First Hospital of China Medical University, Shenyang/CN ,[2]Shengjing Hospital affiliated to China Medical University, Shenyang/CN ,[3]The Second Hospital of Dalian Medical University, Dalian/CN ,[4]Liaoning Cancer Hospital, Shenyang/CN ,[5]Fushun Central Hospital, Fushun/CN

Introduction: This study aims to identify prognostic factors, integrate them into nomograms, and assess the effectiveness of bone-modifying agents (BMAs) in driver-negative NSCLC patients receiving first-line immunotherapy (IO) in real-world setting.

Methods: This retrospective multicenter study included 421 patients with histologically or cytologically confirmed advanced unresectable driver-negative NSCLC who received first-line IO from January 2017 to November 2024. Cox regression analysis was performed to identify independent prognostic factors. Nomograms were developed to predict survival outcomes in NSCLC patients with bone metastasis (BM; the ratio of training and validation cohorts was 6.7: 3.3); the effectiveness of BMAs (denosumab and bisphosphonates) was evaluated in this population.

Results: Among 421 patients with NSCLC, the median follow-up was 16.83 months (95% CI 15.27-18.57), and 213 developed BM; those with BM at baseline had worse survival than those without BM (PFS: 8.63 vs 22.87 months, HR=2.50, p<0.001; OS: 16.83 vs 58.83 months, HR=4.58, p<0.001). Both liver metastasis and BM were significantly independently associated with PFS and OS (all p<0.05). For 213 patients with BM, the nomogram demonstrated good predictive ability of survival; the area under the curve (AUC) in the training group of 6-, 12-, and 18-month PFS was 0.67 (95% CI, 0.57-0.78), 0.79 (95% CI, 0.70-0.87), and 0.83 (95% CI, 0.74-0.91), respectively; the AUC of 6-, 12-, and 18-month OS was 0.76 (95% CI, 0.60-0.92), 0.79 (95% CI, 0.69-0.89), and 0.85 (95% CI, 0.76-0.93), respectively. For patients receiving BMAs, balanced baseline characteristics were observed between the denosumab (n=92) and bisphosphonate (n=121) groups. Both PFS and OS were significantly longer in denosumab than the bisphosphonate groups (PFS: 12.60 vs 8.00 months, HR=1.74, p=0.002; OS: 25.73 vs 14.03 months, HR=3.08, p<0.001). Benefits of the median PFS and OS were observed across the subgroups (almost all p<0.05). No significant difference was observed in ORR and DCR (all p>0.05). A total of 17 of 213 (7.98%) patients experienced skeletal-related events (SREs; denosumab, n=6 [6.52%]; bisphosphonate, n=11 [9.09%]), with no significant difference in the incidence between the two groups. The median time from the start of BMA to SRE was not reached and 40.43 months (95% CI NE) in the denosumab and bisphosphonate groups, respectively (p>0.05).

Conclusions: This study identified the prognostic factors in advanced unresectable driver-negative NSCLC treated with IO and, in patients with BM, proposed a nomogram for estimating survival probabilities and assessed the efficacy of BMAs, offering insights to guide treatment decisions and improve outcomes.

P1.11.29 ICIs Plus Paclitaxel-Based Chemotherapy Is an Optional Treatment for Transformed SCLC After EGFR-TKI

J. Wang, Y. Wang
Peking University Cancer Hospital & Institute, Beijing/CN

Introduction: Small cell lung cancer (SCLC) transformation is one of the acquired resistance mechanisms for epidermal growth factor tyrosin kinase inhibitors (EGFR-TKIs) in non-small cell lung cancer (NSCLC) patients with EGFR sensitive mutations. Etoposide combined with platinum chemotherapy always plays as the first line treatment, while the subsequential line keeps vague.

Methods: Group A was set as aim group, and included patients with SCLC transformation after EGFR-TKI failure and following ICIs plus taxanes-based treatment. In order to analyze whether the addition of ICIs could prolong survival of patients with SCLC transformation, a control group (Group B) was established and included transformed patients who did not receive ICIs treatment after transformation. For the purpose of analyzing the efficacy and survival differences of taxanes-based chemotherapy plus ICIs between patients with and without transformation after EGFR-TKI resistance, we set another control group (Group C: including EGFR-mutant NSCLC patients who did not undergo transformation after EGFR-TKI treatment and received following taxanes-based chemotherapy plus ICIs).

Results: Forty-six patients were enrolled in this study (Group A: N=8; Group B: N=21; Group C: N=17). Seven of eight (7/8, 87.5%) patients in Group A received ICIs plus albumin paclitaxel-based regimens after conventional etoposide/platinum treatment. Patients in Group A tended to achieve a higher DCR than patients in Group B (100% vs 76.2%, p = 0.283), whereas ORRs in these two cohorts were similar (12.5% vs 14.3%, p = 1.000). No significant differences of PFS and OS from the initial diagnosis of advanced stage lung cancer (OS1) were observed between Group A and Group B (median PFS: 5.0 months vs 4.6 months, p = 0.932; median OS1: 54.3 months vs 34.1 months, p = 0.122). OS after transformation in Group A tended to be longer than that in Group B (median OS after transformation: 25.3 months vs 15.0 months, p = 0.055), especially for patients with mono-EGFR-TKI treatment (25.3 months vs 15.0 months, p = 0.010), or without chemotherapy (23.6 months vs 19.1 months, p = 0.045), or without antiangiogenic therapy (23.8 months vs 15.0 months, p = 0.061) before transformation. DCR (100.0% vs 94.1%, p = 1.000) and ORR (12.5% vs 5.9%, p = 1.000) were similar between Group A and Group C with the treatment of taxanes-based chemotherapy and ICIs. Comparable median PFS (5.0 months vs 6.4 months, p = 0.136), median OS1 (54.3 months vs 39.0 months, p = 0.235), and median OS from ICIs implementation (25.3 months vs not reached, p = 0.530) were observed between Group A and Group C.

Conclusions: In EGFR-mutant NSCLC patients with SCLC transformation after EGFR-TKI resistance, ICIs plus taxanes-based chemotherapy is an optional subsequential treatment regimen after conventional etoposide/platinum regimens

P1.11.30 The Efficacy of Immunotherapyfor Patients With Advanced Lung Cancer and Oncogenic Driver Alterations

J. Zhong
Shanghai Chest Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai/CN

Introduction: Immune checkpoint inhibitors (ICIs) targeting the PD-1/PD-L1 axis have become a cornerstone in the management of advanced non-small-cell lung cancer (NSCLC) without driver mutations. However, the therapeutic efficacy in NSCLC harboring oncogenic driver alterations remains inadequately clarified. This study aims to elucidate the clinical effectiveness of ICIs for advanced NSCLC with actionable mutations, providing critical insights into their role in genetically defined NSCLC subsets.

Methods: A retrospective analysis was conducted on patients with advanced NSCLC harboring oncogenic driver mutations who received ICIs at Shanghai Chest Hospital between June 2017 and May 2024. De-identified clinical data were analyzed to assess clinicopathologic characteristics, PD-L1 expression at the initiation of ICI therapy, and treatment outcomes, including best response (RECIST 1.1), progression-free survival (PFS), and overall survival (OS). The last follow-up visit occurred on October 15, 2024, with a median follow-up duration of 20.8 months. Additionally, RNA sequencing (RNA-seq) data from The Cancer Genome Atlas (TCGA) were analyzed to characterize the tumor immune microenvironment(TIME) in NSCLC, with a focus on analyzing TIME associated with various genetic alterations.

Results: A total of 407 patients with advanced NSCLC were retrospectively analyzed, harboring the following oncogenic driver mutations: KRAS (n=152), EGFR (n=146), BRAF (n=16), MET (n=28), HER2 (n=31), ALK (n=16), RET (n=13), and ROS1 (n=5). Of these, 146 patients (35.9%) received ICIs after progressing on prior TKI therapy, with the majority belonging to the EGFR subgroup (n=116, 28.5%). Meanwhile, 261 patients (64.1%) received ICIs as first-line therapy, predominantly in the KRAS subgroup (n=146, 35.9%). Across the entire cohort, the median PFS was 17.0 months, while median OS was not reached (NR) at the time of data cutoff. Mutation-specific median PFS was as follows: 31.3 months for BRAF, 31.5 months for RET, 28.3 months for KRAS, 22.2 months for MET, 16.2 months for HER2, 10.2 months for EGFR, and 6.4 months for ALK.Among EGFR-mutant tumors, median PFS differed by mutation subtype but without statistical significance (P=0.9058): 10.07 months for Exon 19 deletion, 9.40 months for Exon 21 L858R mutation, and 13.1 months for other rare EGFR mutations. PD-L1 expression levels did not significantly correlate with PFS in EGFR-mutant patients (P=0.1195). Among KRAS-mutant tumors, no significant difference in PFS was observed between KRAS G12C (n=56) and other rare KRAS mutations (n=96, P=0.6792). However, PD-L1 expression was significantly associated with prolonged PFS (P=0.0181), with PD-L1-positive patients (>=1%) exhibiting a median PFS of 29.4 months versus 15.5 months in PD-L1-negative cases.RNA-seq analysis from TCGA revealed upregulation of immune effector genes (CD8A, IFNG, CD274, GZMB, CXCL9) in KRAS- and BRAF-mutant tumors, whereas EGFR, ALK, RET, MET, and ROS1 alterations were associated with reduced expression. KRAS- and BRAF-mutant tumors also showed higher enrichment of antitumor pathways, particularly CD8+ T cell and immune checkpoint activation signatures. A meta-analysis of 13 studies confirmed the highest ORRs in KRAS- and BRAF-mutant tumors, aligning with our findings.

Conclusions: These findings underscore the differential response to ICIs based on oncogenic driver mutations, highlighting the importance of molecularly guided treatment strategies to optimize patient outcomes.

P1.11.31 Dynamic Monitoring of Circulating Tumor Cells and Single-Cell Sequencing Predict Therapeutic Efficacy in Advanced Lung Cancer

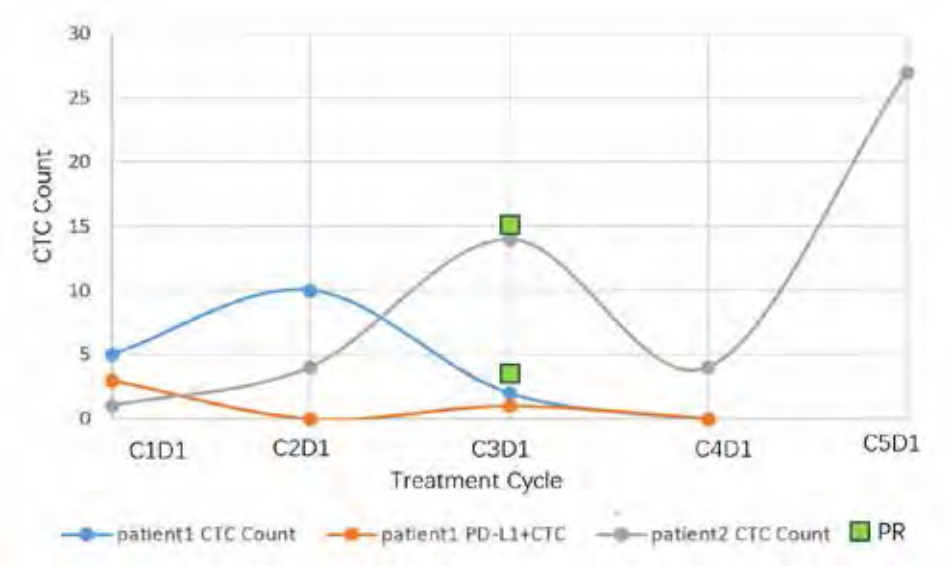
C. Zhao[1], L. Cheng[1], J. Yu[1], G. Gao[1], M. Yang[1], F. Pang[2], C. Zou[2], F. Wu[2], X. Li[1], S. Ren[1]
[1]Shanghai Pulmonary Hospital, Shanghai/CN ,[2]Menarini Silicon Biosystem SpA, Shanghai/CN

Introduction: Circulating tumor cells (CTCs), as an important biomarker in liquid biopsy, demonstrate the predictive role for prognosis. This study further investigated the clinical application scenarios of CTC dynamic monitoring, single-cell isolation, and next-generation sequencing (NGS) in lung cancer.

Methods: From November 2023 to December 2024, 53 patients with advanced lung cancer (30 NSCLC, 23 SCLC) were enrolled. CTC enumeration and PD-L1 expression were assessed using the CellSearch system at baseline (C1D1) and pre-treatment days of subsequent cycles (C2D1-C5D1). Patients with ≥10 CTCs underwent DEPArray-based single-cell isolation followed by whole-exome sequencing (WES).

Results: CTCs were detectable in 90% (27/30) of NSCLC patients(median count of 3, range from 0 to120). Among them, 33% (10/30) having ≥5 CTCs, and 60% (6/10) of these patients exhibited PD-L1+ CTCs. All SCLC patients exhibited baseline CTCs, with a median count of 38 (range from 1 to over 10,000). CTC clearance after two cycles showed an ORR of 80% (4/5) in NSCLC. In SCLC patients with CTC reduction (baseline ≥5 CTCs declining to <5) observed after one cycle (C2D1) showed response rate of 100% (7/7), significantly higher than 44.4% (4/9, p=0.034) in the non-reduction group. Besides the dynamic change of CTC, we observed that the combining of whole-exome sequencing could enhanced the predictive ability for the efficacy of chemotherapy and immunotherapy in 2 cases of advanced NSCLC(Figure 1).

Conclusions: Dynamics CTC testing could early predicte the efficacy of anti-cancer therapy in lung cancer. Besides, further single-cell NGS sequencing enhanced the predictive yields in NSCLC, large scale validating is ongoing in this field.



Keywords: Dynamic monitoring of CTC, Single-cell sequencing, Predictive biomarkers

P1.11.32 Quality of Life Outcomes from the Phase 3 Study of Atezolizumab + Bevacizumab and Chemotherapy (ATTLAS, KCSG-LU19-04) in EGFR/ALK- Mutated NSCLC

Introduction: In the phase 3 ATTLAS study, the combination of atezolizumab with bevacizumab, paclitaxel, and carboplatin (ABCP), followed by maintenance therapy with atezolizumab plus bevacizumab, demonstrated longer progression-free survival and no new safety concerns compared to pemetrexed plus carboplatin or cisplatin (PC), followed by pemetrexed maintenance, in EGFR- or ALK-mutated NSCLC following tyrosine kinase inhibitor (TKI) failure. Here, we report patient-reported quality of life (QoL) outcomes from this trial.

Methods: Patients received intravenous treatment every 3 weeks until disease progression or loss of clinical benefit. The ABCP regimen consisted of atezolizumab (1,200 mg), bevacizumab (15 mg/kg), paclitaxel (175 mg/m^2), and carboplatin (AUC 5 or 5.5). The PC arm included pemetrexed (500 mg/m^2) with either carboplatin (AUC 5.0) or cisplatin (70 mg/m^2). Health-related QoL was assessed at each cycle using the EORTC QLQ-C30 and QLQ-LC13 questionnaires. Key endpoints included changes in global health status/QoL (GHS/QoL) from baseline to weeks 9 and 24, and the median time to deterioration (TTD), defined as a ≥10-point decline in GHS/QoL.

Results: Of 228 patients randomized (2:1), 146 in the ABCP arm and 68 in the PC arm completed at least one QoL assessment. Baseline GHS/QoL scores were similar across arms. The ABCP group showed a slightly greater early decline in GHS and physical functioning scores, but both arms demonstrated trends toward improvement by week 24. Differences in the least squares (LS) mean scores were not statistically significant (Week 9: −4.66 [95% CI, −12.57 to 3.26], P = 0.247; Week 24: −7.39 [−21.72 to 6.94], P = 0.305). QLQ-LC13 results showed more neuropathy, alopecia, and pain in the ABCP arm, suggesting greater treatment-related toxicity. However, cancer-related symptoms (e.g., coughing, hemoptysis, dyspnea) improved more in the ABCP group. Median TTD for GHS/QoL did not differ significantly between arms (P = 0.160).

Conclusions: Despite toxicity-related functional impairment in the ABCP group, overall QoL was not significantly worse compared to the PC group. Improvements in cancer-related symptoms and stable GHS/QoL suggest that ABCP treatment may help maintain QoL while offering survival benefits with appropriate toxicity management.

P1.11.33 The Role of Rhamnose Derived From Gut Microbiome in Modulating the Efficacy of Non-Small Cell Lung Cancer Immunotherapy

X. Han, J. Chen
The Second Affiliated Hospital of Dalian Medical University, Dalian/CN

Introduction: In recent years, the relationship between gut microbiota and metabolites and immunotherapy for non-small cell lung cancer (NSCLC) has gradually become a research hotspot. Rhamnose is a monosaccharide that can be secreted by the gut microbiome and has certain potential in regulating immune responses. The mechanism by which Rhamnose regulates the efficacy of immunotherapy for NSCLC is not yet clear. The aim of this study is to explore the mechanism by which gut microbiome metabolite rhamnose regulates the efficacy of immunotherapy for non-small cell lung cancer, providing new ideas for improving the efficacy of immunotherapy for non-small cell lung cancer.

Methods: According to the progression free survival (PFS) of NSCLC patients after immunotherapy, they were divided into a response group (PFS>6 months, R group) and a non-response group (PFS ≤ 6 months, NR group). Baseline fecal samples were collected from patients for non-targeted metabolomics sequencing to screen for rhamnose. Using a mouse lung cancer model, mice were divided into a control group, a rhamnose group, an anti-PD-1 treatment group, and a combination therapy group (rhamnose +anti-PD-1). Observe the changes in tumor volume in different groups of mice. Flow cytometry and immunohistochemical were used to detect changes in tumor infiltrating CD8+T cells in different groups of mice. ELISA was used to detect the expression levels of IFN - γ and Granzyme B in the plasma of different groups of mice.

Results: Non-targeted metabolomics sequencing found that compared with the NR group, the R group had significantly increased levels of rhamnose. In vivo studies on mice showed that compared to the anti-PD-1 monotherapy group, the combination treatment group showed a significant slowdown in tumor volume growth. The results of flow cytometry and immunohistochemical showed that compared with the anti-PD-1 monotherapy group, the infiltration of CD8+T cells in tumor tissues increased in the combination treatment group. According to the ELISA results, the proportion of IFN - γ and Granzyme B in peripheral blood of the combined treatment group also increased, indicating the regulatory effect of rhamnose on systemic immune response.

Conclusions: The efficacy of NSCLC immunotherapy may be related to gut microbiome metabolite rhamnose. Rhamnose enhances the function of CD8+T cells by increasing tumor infiltration and raising the levels of cytokine IFN-γ and Granzyme B.

P1.11.34 First-Line Camrelizumab Plus Chemotherapy in 3004 Patients With Advanced Non-Squamous NSCLC: A Nationwide Retrospective Study

Z. Wei[1], J. Yu[1], X. Meng[1], X. Liu[1], K. Zhai[1], L. Kong[1], L. Jiang[1], C. Ma[2], W. Zhu[2], J. Li[2]
[1]Shandong Cancer Hospital & Institute, Jinan/CN ,[2]Jiangsu Hengrui Pharmaceuticals Co., Ltd., Shanghai/CN

Introduction: Camrelizumab plus chemotherapy has been approved for the fist-line treatment of advanced non-squamous non-small cell lung cancer (NSCLC) based on the success of the phase 3 CameL study. Recently, the 5-year results from CameL were published. However, long-term outcomes reflecting the effect of this combination strategy in real-world population are warranted.

Methods: This was a nationwide, retrospective observational study of patients with advanced non-squamous NSCLC treated with first-line camrelizumab plus chemotherapy, conducted in China. Baseline characteristics, treatment information, overall survival (OS), and adverse events were reviewed, with indirect descriptive comparisons to CameL.

Results: Between February 28, 2019 and December 29, 2022, a total of 3004 patients from 236 sites initiated treatment. Compared with CameL, the patients in this study were older (median: 65 years vs 59 years; ≥65 years: 51.0% vs. 22.0%). Of these patients, 7.7% of them had an Eastern Cooperative Oncology Group performance status ≥2, while these patients were excluded from CameL. Due to poor tolerance, 5.0% of patients received camrelizumab plus single-agent chemotherapy in this study, while all patients received camrelizumab plus platinum-based doublet chemotherapy in CameL. As of March 5, 2025, the median OS was 25.9 months (95% CI, 24.8-26.8) in 3004 patients, with a median follow-up duration of 25.6 months. In CameL, the median OS was 27.1 months (95% CI, 21.9-31.5) after 5-year results were updated. Of 1002 patients with available safety data in this study, the incidence of any-grade treatment-emergent adverse events (TEAEs) was 78.8%, and 15.7% of patients had grade ≥3 TEAEs.

Conclusions: In real-world setting, more elderly and vulnerable patients received camrelizumab plus chemotherapy. Even under this circumstance, the OS benefit in this study was similar with that in CameL. These large-scale data supported the application of this combination strategy for a broader population in clinical practice. The study is ongoing to enroll more patients and extend follow-up, and 3- to 5-year real-world OS rates will be reported in the future.

P1.11.35 RATIONALE-303: Long-Term Outcomes With Tislelizumab in Previously Treated Advanced or Metastatic Non-Small Cell Lung Cancer

C. Zhou[1], Y. Fan[2], Z. Ma[3], Y. Cheng[4], Y. Wang[5], Y.Y. Bao[6], W. Zheng[7], K. Naicker[8], P.R.M. de Marchi[9]
[1]Shanghai East Hospital, Tongji University School of Medicine, Shanghai/CN ,[2]Cancer Hospital of University of Chinese Academy of Sciences and Zhejiang Cancer Hospital, Hangzhou/CN ,[3]The Affiliated Cancer Hospital of Zhengzhou University/Henan Cancer Hospital, Zhengzhou/CN ,[4]Jilin Cancer Hospital, Changchun/CN ,[5]BeOne Medicines Ltd., Beijing/CN ,[6]BeOne Medicines Ltd., Shanghai/CN ,[7]BeOne Medicines (Beijing), Co., Ltd., Beijing/CN ,[8]BeOne Medicines UK, Ltd., London/GB ,[9]Grupo Oncoclínicas, Rio de Janeiro/BR

Introduction: In the final analysis of RATIONALE-303 (NCT03358875), patients with locally advanced or metastatic squamous or non-squamous non-small cell lung cancer (NSCLC) who progressed after platinum-based chemotherapy experienced significantly improved overall survival (OS) with tislelizumab (an anti-programmed cell death protein-1 antibody) vs docetaxel. RATIONALE-303 met its dual primary endpoints of OS in the intent-to-treat (ITT) population and OS in patients with tumour cell programmed death-ligand 1 (PD-L1) expression of ≥25%. We present long-term efficacy outcomes with an additional 30-month follow-up since the final analysis.

Methods: RATIONALE-303 was a global, open-label, randomised, multicentre, phase 3 trial. Patients aged ≥18 years with histologically confirmed, locally advanced or metastatic (squamous or non-squamous) NSCLC who progressed on prior platinum-based chemotherapy were randomised (2:1) to receive intravenous tislelizumab 200 mg or docetaxel 75 mg/m2 every 3 weeks. Co-primary endpoints were OS in the ITT population and PD-L1 ≥25% populations. Secondary endpoints were investigator-assessed progression-free survival (PFSINV), objective response rate (ORRINV), duration of response (DoRINV), and safety.

Results: As of January 18, 2024, median follow-up for OS was 46.5 and 46.7 months for tislelizumab and 41.0 and 41.6 months for docetaxel in the ITT (tislelizumab, n=535; docetaxel, n=270) and PD-L1 ≥25% (tislelizumab, n=227; docetaxel, n=115) populations, respectively (by reverse Kaplan-Meier method). Tislelizumab-treated patients experienced sustained clinical benefit vs docetaxel (Table). Respective median OS was 16.9 vs 11.9 months (stratified HR=0.67; 95% CI: 0.57, 0.80; P<.0001) in the ITT population and 19.3 vs 11.5 months (stratified HR=0.52; 95% CI: 0.40, 0.68; P<.0001) in patients with PD-L1 ≥25%. In the ITT population, median PFSINV was significantly higher with tislelizumab vs docetaxel (4.2 vs 2.6 months [HR=0.64; 95% CI: 0.54, 0.76; P<.0001]); ORRINV (22.6% vs 7.8%) and median DoRINV (13.5 vs 6.1 months) were also higher with tislelizumab vs docetaxel. Tislelizumab-treated patients experienced a lower incidence of grade ≥3 treatment-emergent adverse events (43.6% vs 74.8%) and treatment-related grade ≥3 events (16.1% vs 66.3%) vs docetaxel-treated patients. No new safety signals were identified.

Conclusions: After an additional 30 months' follow-up since the final analysis, previously treated patients with advanced or metastatic NSCLC in the ITT and PD-L1 ≥25% populations of RATIONALE-303 continued to experience a clinically meaningful improvement in OS with tislelizumab vs docetaxel. Tislelizumab-treated patients also had higher response rates, more durable responses, delayed disease progression, and a favourable safety profile compared with docetaxel. These results further support tislelizumab as a treatment option for this patient population.

Table. Efficacy Outcomes in the RATIONALE-303 Trial

	ITT Population		PD-L1 ≥25% Population	
	Tislelizumab (n=535)	Docetaxel (n=270)	Tislelizumab (n=227)	Docetaxel (n=115)

Introduction: Real-world evidence (RWE) is increasingly recognized as a vital complement to randomized clinical trials in guiding regulatory and reimbursement decisions. The Food and Drug Administration of the United States (FDA), Health Canada, the European Medicines Agency (EMA) and other regulatory agencies encourage integration of RWE into submissions for new therapeutic indications as well as funding recommendations. The Pan-Canadian Lung Cancer Observational Study (PALEOS) and the Pulse Infoframe Lung Cancer Registry aim to generate critical RWE to meet the needs of regulatory review.

Methods: PALEOS is a multicenter observational registry study being conducted at several Canadian centres collecting both retrospective and prospective real-word data (RWD) on non-small cell lung cancer (NSCLC), following receipt of appropriate ethics and institutional approvals (NCT04706754). The registry captures close to 500 data elements including clinical and demographic variables, diagnostic and molecular profiles, treatment pathways, healthcare utilization patterns and patient reported outcomes (EQ-5D-5L, FACT-L) using both retrospective and prospective methods. Currently, the six initial PALEOS sites centres provide healthcare services to some of the most populous regions in the country and represent a catchment of about thirty percent of the Canadian population, including a mix of urban and rural populations. PALEOS is in the process of engaging additional centers in Canada and internationally for expansion in 2025.

Results: Following activation at the first site in 2019, this lung cancer registry has grown to 2,225 patients as of April 2025. Current registry demographics at first presentation to the cancer centre are: median age at diagnosis of 69 years (range 22-96; n=1684); 48.2% female; and 19.2% stage I, 8.2% stage II, 17.9% stage III, and 58.0% stage IV (n=1381). PD-L1 staining was 29.0%, 31.3% and 39.7% for <1%, 1-49% and ≥50% staining categories, receptively (n=1005). First-line metastatic treatment involving immunotherapy was received by 44.2% of patients (23.1% chemoimmunotherapy, 21.1%, PD-L1 monotherapy), and a further 37.6% received chemotherapy, and 18.2% targeted therapy (n=968). Median follow-up was 18 months for stage I-III patients (range 0-182 months) and 7.6 months (range 0-196 months) for stage IV patients. Median overall survival for stages I, II, III, IV were 46.1, 33.0, 16.4, and 9.7 months, respectively.

Conclusions: PALEOS establishes a robust framework to examine the natural progression, diagnostic and therapeutic approaches, treatment outcomes, and patient reported outcomes in the varied subsets of patients with lung cancer in Canada. It aims to deepen insights into the ways that novel diagnostic tools and treatments inform real-world clinical practice. The project supports the translation of evidence into clinical practice and strengthens data-driven decision-making in multidisciplinary lung cancer care. Moreover, this RWD is collected in a structured registry platform enabled to support regulatory and funding decisions.

Introduction: Immunotherapy has revolutionized the treatment landscape for advanced non-small cell lung cancer (NSCLC). Since the European Medicines Agency's first approval in 2016, immunotherapy use has extended across all lung cancer histologies and stages. This retrospective analysis from the Spanish Lung Cancer Group's Thoracic Tumor Registry assesses first-line immunotherapy impact on real-world advanced NSCLC patients.

Methods: We analyzed 6,483 patients with advanced NSCLC: 2,803 (43.2%) received immunotherapy and 3,680 (56.8%) did not. We assessed immunotherapy's impact on overall survival (OS) and progression-free survival (PFS), and established correlations between response parameters and long-term survival. We also analyzed clinical characteristics associated with immunotherapy benefit. Kaplan-Meier curves were used for survival analyses with hazard ratios (HRs) derived from Cox proportional hazards models. Statistical significance was set at $p<0.05$.

Results: Baseline characteristics were well-balanced between groups, with predominantly male patients (75.3%), median age of 64 years, and >90% current/former smokers. Most patients had ECOG Performance Status 0-1. Immunotherapy significantly improved OS compared to chemotherapy alone (median OS: 16.3 vs. 10.1 months; HR 0.69, 95% CI 0.64-0.73; $p<0.001$). The 12-month OS rates were 60.7% vs. 43.5%, and 24-month OS rates were 36.3% vs. 23.7% in immunotherapy and control groups, respectively. For PFS, immunotherapy showed modest improvement (median PFS: 9.1 vs. 7.4 months; HR 0.94, 95% CI 0.88-1.00; $p=0.053$). Univariate analysis identified factors associated with OS. Poor prognostic factors in both groups included ECOG PS >1, bone metastases, liver metastases, multiple metastatic sites (>3), and more than three comorbidities. Gender and age were associated with prognosis in the chemotherapy arm but not in the immunotherapy arm. Treatment response strongly predicted survival, with complete response being associated with the most favorable outcomes in both groups.

Conclusions: This real-world analysis confirms that immunotherapy provides significant survival benefits for patients with advanced NSCLC compared to chemotherapy alone. The substantial improvement in median OS demonstrates clinically meaningful benefits of immunotherapy, and treatment response strongly predicts survival.

P1.11.38 Measuring the Effect of Age and Ethnicity on Outcomes in Patients With Advanced Lung Cancer Treated With Immunotherapy: A New Zealand Analysis

R. Cole[1], A. Tan[2], M. Marshall[3], A. Wong[4], E. Brenman[1]
[1]Te Whatu Ora, Tauranga/NZ ,[2]Te Whatu Ora, Hamilton/NZ ,[3]Te Whatu Ora, Auckland/NZ ,[4]Te Whatu Ora, Wellington/NZ

Introduction: Regimens including immunotherapy are the standard first line option for advanced non small cell lung cancer. Pembrolizumab became publicly funded for this indication in New Zealand on 1 April 2023. We investigated the effect of ageing, ethnicity, and other factors on outcome in the New Zealand population.

Methods: This multicentre retrospective cohort study included all patients treated for advanced lung cancer with publicly funded pembrolizumab +/- chemotherapy in part of New Zealand from 1 April 2023 - 31 March 2024. Follow up ended at 1 October 2024. The primary endpoint was time to treatment failure (TTTF). Overall survival was a secondary endpoint.

Results: 125 patients were included with a median age of 68 years (range 48-85). 51 (41%) of patients were New Zealand Māori. The median TTTF was 12.8 months (95% Confidence Interval [CI] = 10.2 to 15.2). Using multivariate analysis, the risk factors for TTTF were age <70 years HR 2.13 (95% CI 1.18 to 3.85, p=.013), non-Māori ethnicity HR 1.78 (95% CI 1.05 to 3.00, p=.031), ECOG 2+ HR 3.08 (95% CI 1.31 to 7.23, p=.010) and high Charlson Comorbidity Index HR 2.67 (95% CI 1.12 to 6.38, p=.027). The risk factors for death were non-Māori ethnicity HR 2.68 (95% CI 1.24 to 5.78, p=.012), ECOG 2+ HR 7.58 (95% CI 2.12 to 27.1, p=.002) and immunotherapy monotherapy HR 2.59 (95% CI 1.33 to 5.06, p=.005). Patients >70 years had no difference in probability of death (p=0.224).

Conclusions: In this cohort of patients, when adjusting for multiple confounders, the duration of treatment was longer for older patients. However, age had no significant influence on survival. Māori patients had a longer duration of treatment and were less likely to die than non-Māori patients. Poor performance status was the greatest overall predictor of death. These results contribute to a growing body of evidence that advancing age has limited influence on overall outcome in patients treated with immunotherapy. That Māori patients had increased survival is encouraging, given this group typically has poorer health outcomes than non-Māori.

Introduction: Lung cancer is the leading cause of cancer-related mortality, with brain metastases (BMs) worsening prognosis and quality of life. Immune checkpoint inhibitors (ICIs) have transformed the treatment of non-small cell lung cancer (NSCLC), but precise prognostic tools are needed to optimize decision-making.

Methods: The Brain-Lung Immunotherapy Prognostic (BLIP) score was developed using a retrospective cohort of NSCLC patients treated with ICIs at Karolinska University Hospital, Sweden. Prognostic factors were identified through univariate and multivariate Cox regression analyses. Internal validation utilized bootstrap resampling, penalized Cox regression, k-fold cross-validation, and receiver operating characteristics (ROC) analysis. External validation was conducted using an independent cohort from Sotiria Thoracic Diseases Hospital of Athens, Greece.

Results: Among 1844 patients screened, 152 from Karolinska University Hospital and 116 from Sotiria Thoracic Diseases Hospital were included. Key prognostic factors included histology, actionable mutations, age at BM diagnosis, and number of BMs. The BLIP score stratified patients into two prognostic groups: “Good” and “Poor,” with median overall survival (OS) of 15 and 7 months, respectively (hazard ratio [HR]: 0.4; $p < 0.0001$). External validation confirmed these findings, with a significantly lower risk of death for the “Good” group (HR: 0.49; $p = 0.0063$). The model showed robust performance (area under the ROC curve: 0.87).

Conclusions: The BLIP score is a validated prognostic tool for NSCLC patients with BMs receiving ICIs. Incorporating clinical and molecular factors, it improves existing models and supports personalized treatment strategies.

Introduction: Pemetrexed-based chemoimmunotherapy (CI) represents a standard regimen for treating advanced non-squamous non-small cell lung cancer (NSCLC). However, its use necessitates caution in individuals with impaired renal function. This study investigated how different methodologies for evaluating renal function influence clinical outcomes in patients with NSCLC exhibiting low programmed death-ligand 1 (PD-L1) expression.

Methods: A total of 352 patients treated between May 2018 and June 2023 were analyzed. Renal function was assessed by both enzymatic and Jaffe methods, and patients were categorized into three groups: Cohort A (Ccr > 50 mL/min by both methods), Cohort B (Ccr > 50 by enzymatic but ≤ 50 by Jaffe), and Cohort C (Ccr ≤ 50 by both methods). Progression-free survival (PFS) was compared between PEM-based and non-PEM-based CI groups before and after propensity score matching (PSM), adjusting for age, ECOG PS, histology, and driver mutation status.

Results: In the overall cohort, PEM-based CI was associated with significantly longer PFS than non-PEM-based CI (median 8.9 vs. 6.9 months, p = 0.003). However, in subgroup analyses, this benefit was clearly observed only in Cohort A (9.4 vs. 7.4 months, p = 0.011). In Cohort B (n = 59), where renal function appeared adequate enzymatically but impaired by the Jaffe method, no significant difference in PFS was observed between treatment groups (6.9 vs. 6.3 months, p = 0.268). Similarly, in Cohort C (n = 29), PFS did not significantly differ between groups (13.8 vs. 6.4 months, p = 0.158), though the sample size was limited. These findings suggest that PEM-based regimens may offer limited benefit in patients with marginal or impaired renal function not detectable by enzymatic assessment alone. After PSM, 178 patients (89 per group) were matched. In the matched cohort, PEM-based CI was associated with slightly longer PFS (8.5 vs. 7.0 months, p = 0.049). In matched Cohort A (n = 132), a similar trend toward improved PFS was seen (8.9 vs. 7.4 months, p = 0.085). In matched Cohorts B and C, the differences in PFS remained non-significant.

Conclusions: These results highlight the clinical relevance of dual-method renal function assessment using both enzymatic and Jaffe techniques. Accurate evaluation is essential for guiding therapeutic decisions and improving treatment efficacy in NSCLC patients with low PD-L1 expression.

P1.11.41 Intrapleural Dual Blockade of IL-6 and PD-L1 Reprograms CAF Dynamics and the Tumor Microenvironment in Malignant Pleural Effusion

P. Zhan, Q. Cheng
Jinling Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing/CN

Introduction: Malignant pleural effusion (MPE) is a severe complication in lung cancer, characterized by an immunosuppressive tumor microenvironment (TME) and limited therapeutic options. This study investigates the role of IL-6 in regulating immune suppression and tumor progression in MPE and evaluates the efficacy of dual IL-6 and PD-L1 blockade.

Methods: IL-6 levels were measured in MPE and paired serum samples from lung cancer patients, and correlations with PD-L1 expression and clinical outcomes were analyzed using publicly available datasets. RNA sequencing and immune deconvolution were used to assess immune cell infiltration. CAFs and immune cell infiltration were further evaluated using flow cytometry, immunohistochemistry, and multiplex immunofluorescence. In vitro co-culture systems were employed to simulate the MPE microenvironment and explore IL-6 interactions with CAFs, as well as its regulatory effect on tumor cell PD-L1 expression.

Results: IL-6 levels were significantly elevated in MPE compared to paired serum and correlated with higher PD-L1 expression and poor survival outcomes in lung cancer patients. In the MPE mouse model, combination therapy with IL-6 and PD-L1 blockade reduced MPE volume, tumor burden, and PD-L1 expression, while enhancing T cell infiltration and alleviating TME immunosuppression. IL-6 was found to drive a positive feedback loop with iCAFs, promoting an immunosuppressive environment. In vitro, IL-6 from the MPE upregulated tumor cell PD-L1 expression the IL-6/STAT3 pathway.

Conclusions: This study identifies IL-6 as a critical contributor of immune suppression and tumor progression in MPE. The combination of IL-6 and PD-L1 blockade effectively alleviated immunosuppression and reduced tumor burden, offering a potential therapeutic approach for MPE management.

P1.11.42 Dual Immune Checkpoint Blockade With CTLA-4 and PD-(L)1 Inhibitors in NSCLC: A Reconstructed Patient Data Meta-Analysis

A. Di Federico[1], S. Stumpo[1], F. Mantuano[1], A. De Giglio[1], F. Lo Bianco[1], F. Pecci[2], J.V. Alessi[3], X. Wang[4], F. Sperandi[5], B. Melotti[5], F. Gelsomino[5], F. Skoulidis[6], M.C. Garassino[7], S. Peters[8], M.M. Awad[9], A. Ardizzoni[1], B. Ricciuti[2]
[1]University of Bologna, Bologna/IT ,[2]Dana-Farber Cancer Institute, Boston/MA/USA ,[3]Hospital Sirio-Libanes, San Paolo/BR ,[4]Harvard University, Boston/MA/USA ,[5]IRCCS Policlinico S.Orsola-Malpighi, Bologna/IT ,[6]MD Anderson Cancer Center, Houston/TX/USA ,[7]University of Chicago, Chicago/IL/USA ,[8]Lausanne University Hospital, Lausanne/CH ,[9]Memorial Sloan Kettering Cancer Center, New York/NY/USA

Introduction: immune checkpoint inhibitors (ICIs) targeting PD-1 or PD-L1, either as monotherapy or in combination with CTLA-4 inhibitors and/or chemotherapy, are the standard of care for patients with advanced non-small cell lung cancer (NSCLC). However, it remains unclear whether dual checkpoint blockade with CTLA-4 and PD-(L)1 inhibitors offers similar efficacy to single PD-(L)1 inhibition or if these approaches yield different outcomes across NSCLC subpopulations.

Methods: We conducted a systematic review and reconstructed individual patient data (IPD) meta-analysis of trials evaluating dual or single immune checkpoint blockade in patients with NSCLC, focusing on studies reporting 5-year survival outcomes or biomarker analyses based on KRAS and/or STK11 mutational status. IPD were extracted and reconstructed by published Kaplan-Meier graphs with respective number at risk at each timepoint using WebPlotDigitizer v5 and the IPDfromKM method, as previously validated.

Results: In total, 6 randomized clinical trials were included in the analyses. Among 2,881 patients with advanced NSCLC, patients who received dual CTLA-4 and PD-(L)1 blockade (n=1,282) achieved similar median OS compared to those who received single PD-(L)1 inhibition (n=1,599) (16.1 versus 16.9 months; HR 0.95, 95% CI, 0.87-1.03, P=0.19), with 3-year OS rates of 29.2% versus 27.0%, respectively, and 5-year OS rates of 19.8% versus 16.3%, respectively. However, among patients with PD-L1 tumor proportion score (TPS) <1%, those who received dual CTLA-4 and PD-(L)1 blockade (n=447), compared to those who received single PD-(L)1 inhibition (n=512), achieved significantly longer median OS (15.5 versus 14.5 months; HR 0.85, 95% CI, 0.74-0.98, P=0.02), with 3-year OS rates of 26.8% versus 18.7%, respectively, and 5-year OS rates of 16.6% versus 9.3%, respectively. Similarly, in patients with NSCLC harboring STK11 mutations, dual CTLA-4 and PD-(L)1 blockade led to significantly longer median OS compared to single PD-(L)1 inhibition (13.9 versus 7.8 months; HR 0.67, 95% CI, 0.49-0.91, P=0.01), with 2-year OS rates of 30.9% versus 22.7%, respectively, and 5-year OS rates of 28.4% versus 13.4%, respectively. No differences in OS between dual CTLA-4 and PD-(L)1 blockade and single PD-(L)1 inhibition were noted among patients with PD-L1 TPS ≥1% (16.5 versus 18.1 months; HR 0.97, 95% CI, 0.88-1.08, P=0.60), TPS 1-49% (15.5 versus 17.3 months; HR 1.02, 95% CI, 0.87-1.20, P=0.77), or TPS ≥50% (19.4 versus 20.3 months; HR 0.96, 95% CI, 0.82-1.12, P=0.62), or based on histology (squamous: 13.6 versus 14.3 months; HR 1.01, 95% CI, 0.88-1.16, P=0.86; non-squamous: 18.3 versus 19.1 months; HR 0.93, 95% CI, 0.84-1.03, P=0.17), KRAS mutational status (KRAS mutated: 20.0 versus 14.8 months; HR 0.84, 95% CI, 0.64-1.10, P=0.20; KRAS wild-type: 16.7 versus 19.9 months; HR 1.10, 95% CI, 0.92-1.31, P=0.29), and in STK11 wild-type tumors (17.4 versus 20.4 months; HR 1.04, 95% CI, 0.87-1.26, P=0.65).

Conclusions: Dual immune checkpoint blockade with CTLA-4 and PD-(L)1 inhibitors, compared to single PD-(L)1 inhibition, is associated with improved OS in patients with advanced NSCLC with PD-L1 TPS <1% and in those harboring STK11 mutations.

Keywords: CTLA-4, immunotherapy, STK11

P1.11.43 Analysis of Characteristics and Predictive Factors for Long-Term Benefit of Immunotherapy in Advanced NSCLC

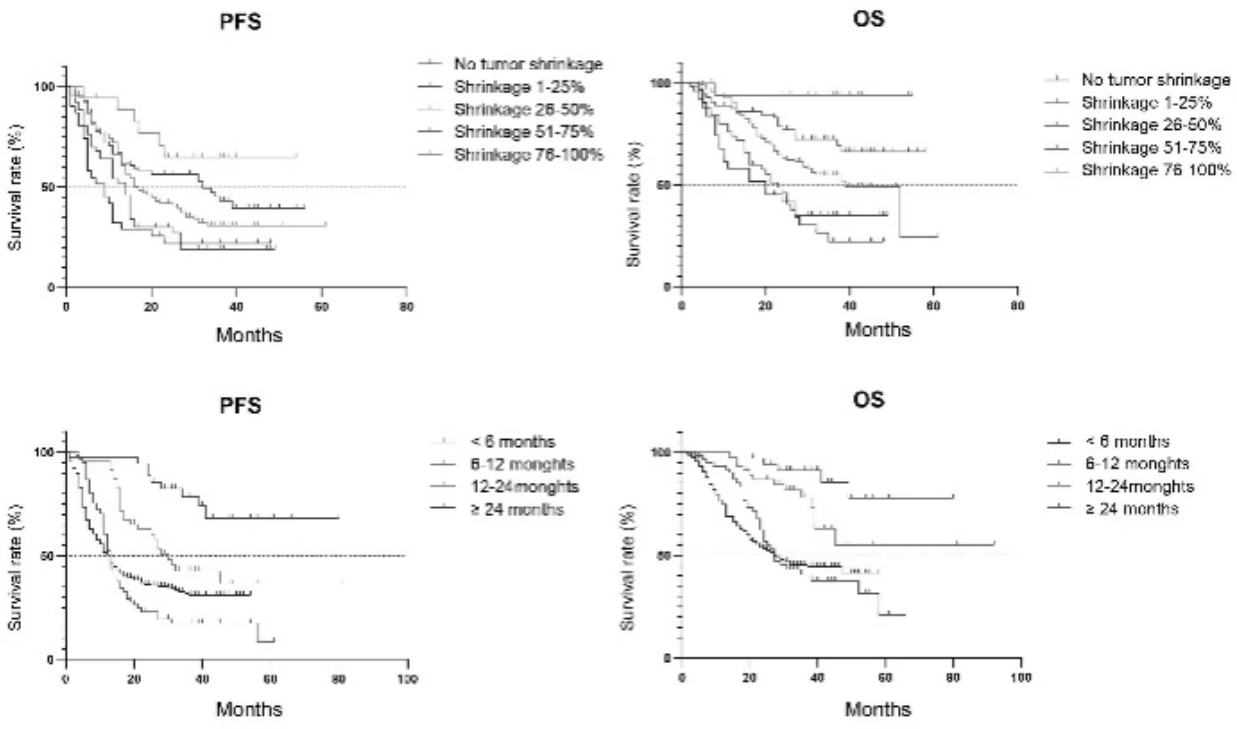
W. Song, H. Wang, J. Cui
The First Hospital of Jilin University, Changchun/CN

Introduction: Currently, there is a lack of sufficient evidence - based medical evidence regarding the commonalities among the population with long - term benefits from immunotherapy and the predictive factors for efficacy. This study aims to explore the clinical characteristics of patients with advanced non - small cell lung cancer (NSCLC) who show a long - term response to immune checkpoint inhibitors (ICIs) treatment.

Methods: This study retrospectively analyzed 372 patients with advanced NSCLC who received first - line ICIs treatment in our hospital. The patients were divided into two groups according to whether their progression - free survival (PFS) reached 24 months. COX regression analysis was used to evaluate the effects of different depths of response (DepOR) and treatment duration on the patients' survival.

Results: During a median follow-up of 36 months, the median OS for patients with PFS ≥ 24 months has not yet been reached, while the median OS for patients with PFS < 24 months was 19 months. The median PFS for the two groups was not reached and 9 months, respectively. According to the maximum percentage reduction of target lesions compared with the baseline, the median DepOR of the group with PFS ≥ 24 months was significantly better than that of the group with PFS < 24 months (48% vs. 34%, P < 0.001). The PFS and overall survival (OS) of the groups with tumor shrinkage of 26% - 50%, 51% - 75%, and 76% - 100% were significantly better than those of the no tumor shrinkage group. The hazard ratios (HR) for PFS were 0.525, 0.475, and 0.265 respectively; the HR for OS were 0.380, 0.270, and 0.048 respectively. The median time for the tumor to shrink to the maximum extent was 18.4 weeks. Compared with the group with treatment duration < 6 months, the PFS and OS of the 12 - 24 months and ≥ 24 months groups were significantly improved (P < 0.05). The HR for PFS were 0.458 and 0.164 respectively; the HR for OS were 0.335 and 0.133 respectively. Continuing treatment after 24 months of medication did not significantly improve OS (P = 0.148).

Conclusions: The population with long - term benefits from immunotherapy showed a deeper degree of tumor response, and the increase in DepOR showed a step - wise improvement in PFS. Prolonging the duration of immunotherapy significantly improved the patients' survival.



Keywords: NSCLC, ICIs, DepOR

P1.11.44 Efficacy and Safety of Immunotherapy as First-Line Treatment in Metastatic Pulmonary Large-Cell Neuroendocrine Carcinoma

H. Yang[1,2], B. Li[1], T. Dong[3], C. Jiang[4], J. Yu[1], L. Wang[1]
[1]Shandong Cancer Hospital and Institute, Jinan/CN ,[2]Shandong First Medical University and Shandong Academy of Medical Sciences, Jinan/CN ,[3]Qilu Hospital of Shandong University, Jinan/CN ,[4]Shandong Provincial Hospital Affiliated to Shandong First Medical University, Jinan/CN

Introduction: Pulmonary large-cell neuroendocrine carcinoma (LCNEC) is a rare and aggressive cancer with a poor prognosis and limited treatment options. The first-line therapy for advanced LCNEC remains uncertain. This study aimed to evaluate the efficacy and safety of combining PD-1/PD-L1 inhibitors with chemotherapy in the first-line setting for patients with metastatic LCNEC.

Methods: This retrospective study included patients with advanced LCNEC treated with either immunotherapy plus chemotherapy (ICT group) or chemotherapy alone (CT group) as first-line therapy. Data from electronic health records of three hospitals, spanning from January 2015 to October 2024, were analyzed. Outcomes including progression-free survival (PFS), overall survival (OS), objective response rate (ORR), and disease control rate (DCR) were assessed for both groups. Safety was monitored in all patients who received at least one dose of the assigned treatment.

Results: A total of 130 patients were enrolled, with 54 assigned to the ICT group and 76 assigned to the CT group. The median PFS (mPFS) was 7.9 months (95% CI, 4.8-10.9) in the ICT group, compared to 5.3 months (95% CI, 3.7-6.9) in the CT group (hazard ratio [HR], 0.642; 95% CI, 0.438-0.941; p = 0.022). The median OS (mOS) was 15.4 months (95% CI, 6.0-24.8) in the ICT group, compared to 19.5 months (95% CI, 13.5-25.5) in the CT group (hazard ratio [HR], 1.040; 95% CI, 0.659-1.641; p = 0.865). The ORRs in the two groups were 55.6% and 46.1%, respectively (p = 0.286), and the DCRs were 87.0% and 78.9%, respectively (p = 0.234). In the CT group, the mOS for patients who received immunotherapy at second-line or later-line was 19.6 months (95% CI: 13.6-25.6), whereas the mOS for patients who received chemotherapy alone after disease progressed was 12.3 months (95% CI: 6.5-18.1) (p = 0.378). Regarding safety, the most frequent grade ≥ 3 adverse events were neutropenia, leukopenia, anemia, and fatigue, with no significant differences between the two groups. Immune-related adverse events (irAEs) in the immunotherapy group included cutaneous hemangiomas, hypothyroidism, anaphylaxis, and pneumonitis, with no grade 3 or 4 irAEs observed. No new safety signals were observed.

Conclusions: First-line treatment combined with a PD-1/PD-L1 inhibitor was associated with superior PFS for advanced LCNEC, but did not significantly improve OS compared to chemotherapy alone.

P1.11.45 Real-World Prognosis of Non-Squamous NSCLC Patients With Liver, Bone, or Brain Metastases Treated With Frontline Therapies

M. Cai, C. Feng, M.A. Clarke, A. Mulina, S. Jha, C. Ferlini
AbbVie Inc., North Chicago/IL/USA

Introduction: Non-small cell lung cancer (NSCLC) commonly spreads to the bone, brain, and liver. Despite advances in therapies, few patients with metastatic NSCLC experience long-term benefit. Metastatic sites have been shown to impact survival, with brain, liver and bone metastases linked to poorer prognosis; however, the effect of metastatic sites on outcomes to treatments is unclear. We used real-world data to assess the influence of metastatic site on outcomes to first line(1L) pembrolizumab(P), chemotherapy(C), or P+C in metastatic NSCLC.

Methods: A retrospective study conducted using the Optum's de-identified Market Clarity Data (Optum® Market Clarity) of adults (≥18 years) with non-squamous, metastatic NSCLC. Eligible patients had ≥1 metastatic site and received P+C, P, or C as 1L therapy between 2017-June 2023. Kaplan-Meier methodology was used to estimate median overall survival (mOS) and 3-year OS by metastatic site and treatment. The ratio of median survival time was calculated by metastatic site using C as reference (REF).

Results: In total, 1,968 patients initiating P+C(44%), P(25%), or C(31%) were included. Median age: 67 years; 45% female. The most common metastatic sites were bone(46%) and brain(42%), followed by liver(17%). Patients receiving P+C and P were more likely to be diagnosed with de novo metastatic NSCLC (72% and 68%, respectively) compared with C(42%). P+C and C patients were similar in age (median: 66 years) and performance status (PS) (77% PS 0-1) compared with P (median: 71 years, 67% PS 0-1). Baseline tumor proportion score for P was more likely to be ≥50% compared with P+C (88% and 33%, respectively). P+C and P patients had a higher likelihood of liver metastases than C patients (19% and 18% vs 12%, respectively), and higher likelihood of bone metastases (51% and 48% vs 37%, respectively). Brain metastases were similar across treatments. Patients who were negative for liver/bone metastases had a numerically longer mOS and 3-year OS vs positive patients across all treatments; the effect was more limited for brain metastases (Table). Longer mOS was observed with P+/- C vs C alone in patients with liver/bone metastases, although the ratio was not statistically significant. No benefit of P+/-C vs C was observed in the metastases-negative treatment groups.

Conclusions: This real-world analysis emphasizes the impact of liver, bone, and brain metastases on prognosis and outcomes to treatment in patients receiving 1L P+/-C. Adding immunotherapy to the C backbone had limited survival benefit, underscoring an unmet medical need in metastatic NSCLC.

P1.11.46 RATIONALE-303: Post-Hoc Analysis of Tislelizumab Monotherapy in Previously Treated Non-Small Cell Lung Cancer With Metastases

D. Huang[1], C. Zhou[2], Y. Fan[3], Z. Ma[4], Y. Cheng[5], M. Austin Taylor[6], J. Wu[6], K. Naicker[7], C.M. de Cerqueira Mathias[8]
[1]Lung Cancer Diagnosis and Treatment Centre, Key Laboratory of Cancer Prevention and Therapy, Tianjin Medical University Cancer Institute and Hospital, National Clinical Research Centre for Cancer, Tianjin/CN ,[2]Shanghai East Hospital, Tongji University School of Medicine, Shanghai/CN ,[3]Cancer Hospital of University of Chinese Academy of Sciences and Zhejiang Cancer Hospital, Hangzhou/CN ,[4]The Affiliated Cancer Hospital of Zhengzhou University/Henan Cancer Hospital, Zhengzhou/CN ,[5]Jilin Cancer Hospital, Changchun/CN ,[6]BeOne Medicines USA, Inc., Cambridge/MA/USA ,[7]BeOne Medicines UK, Ltd., London/GB ,[8]Grupo Oncoclínicas, Salvador/BR

Introduction: The global, open-label, randomised, multicentre phase 3 RATIONALE-303 trial (NCT03358875) demonstrated superior overall survival (OS) with tislelizumab (anti-programmed cell death protein-1 antibody) vs docetaxel in patients with locally advanced or metastatic (squamous or non-squamous) non-small cell lung cancer (NSCLC) who progressed after platinum-based chemotherapy. Results are reported on subgroup analyses of patients with metastases, including liver metastases, who historically have poor prognosis.

Methods: Eligible patients aged ≥18 years were randomised (2:1) to receive intravenous tislelizumab 200 mg or docetaxel 75 mg/m2 once every 3 weeks. Efficacy (OS and investigator-assessed progression-free survival [PFSINV] and objective response rate [ORRINV]) and safety outcomes were analysed based on the number of metastatic sites (locally advanced [ie, no metastatic sites], one or two metastatic sites, or three or more metastatic sites) and presence or absence of liver metastases at baseline.

Results: Among the 805 randomised patients (tislelizumab, n=535; docetaxel, n=270), 106 (13.2%) had liver metastases at baseline (tislelizumab, n=73; docetaxel, n=33). As of January 18, 2024 (median study follow-up: 16.6 months for tislelizumab and 10.7 months for docetaxel), sustained OS, PFSINV, and ORR benefit was observed among tislelizumab- vs docetaxel-treated patients, regardless of the number of metastatic sites at baseline (Table 1). OS, PFSINV, and ORR benefit among patients treated with tislelizumab vs docetaxel was maintained in those with and without liver metastases at baseline (Table 2). Safety outcomes were consistent with the known safety profile of tislelizumab, with tislelizumab demonstrating a more favourable safety profile compared with docetaxel across all subgroups (Tables 1 and 2).

Conclusions: This post-hoc analysis of RATIONALE-303 demonstrated a clinically meaningful OS, PFSINV, and ORRINV benefit with tislelizumab vs docetaxel in pretreated patients with locally advanced or metastatic squamous or non-squamous NSCLC, regardless of the number of metastatic sites, including liver metastases.

P1.11 METASTATIC NON-SMALL CELL LUNG CANCER – IMMUNOTHERAPY
SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.11.47 Clinical Outcomes of Immune Checkpoint Inhibitors Treatment for Postoperative Recurrence in Non-Small Cell Lung Cancer

Y. Imamura, T. Kato, T. Ryo, S. Okado, Y. Nomata, H. Takenaka, H. Watanabe, Y. Kawasumi, K. Nakanishi, Y. Kadomatsu, H. Ueno, S. Nakamura, T. Mizuno, T. Yoshikawa
Nagoya University Hospital, Nagoya/JP

Introduction: The efficacy of immune checkpoint inhibitors (ICIs) in the treatment of non-small cell lung cancer (NSCLC) has been widely reported, but specific advantage of ICIs treatment for postoperative recurrence of NSCLC remains unclear. The aim of the study was to evaluate the efficacy of ICIs treatment in patients with postoperative recurrence of epidermal growth factor receptor (EGFR) wild-type NSCLC.

Methods: A retrospective analysis was performed on 1832 patients with stage I-III NSCLC who underwent anatomical lung resection at our institution between 2013 and 2022. One hundred seven patients with wild-type EGFR NSCLC who experienced postoperative recurrence and underwent ICIs treatment or chemotherapy were included. Patients were divided into those who received ICIs treatment with or without chemotherapy (ICIs group, n = 73) and those who received chemotherapy only (non-ICIs group, n = 34). The following information was collected from the medical records: age, sex, brinkman index, surgical procedure, histopathological findings, programmed death ligand 1 (PD-L1) status, mutations in driver genes, performance status (PS) at recurrence, treatment histories, and survival outcomes. This study evaluated the prognosis for postoperative recurrence, including ICIs treatment and other clinicopathological factors.

Results: In the ICIs group (n = 73), 8 patients were treated with ICIs only, 54 combined with platinum-based chemotherapy and 11 with other chemotherapy. In the non-ICIs group (n = 34), 24 patients were treated with platinum-based chemotherapy and 10 with other chemotherapy. With regard to patient background, the proportion of patients with a history of interstitial lung disease (ILD) was significantly lower in the ICIs group (ICIs group 2.8% vs. non-ICIs group 16.7%, p=0.01). Whereas, other factors showed no significant differences between the two groups. The ICIs treatment significantly prolonged survival after recurrence (median survival: ICIs group 38.8 months vs. non-ICIs group 16.4 months, p<0.01). The same significant differences in prognosis were found in cases excluding ILDs (median survival: ICIs group 38.9 months vs. non-ICIs group 17.2 months, p=0.02). In the subgroup analysis of the ICIs group, no significant differences in survival after recurrence were detected between patients with different PD-L1 status (Tumor Proportion Scores: <1%, 1%-49%, ≥50%, p=0.21). Multivariate analysis of all included cases revealed that postoperative distant recurrence at first occurrence (HR=1.75, 95% CI=1.01-3.03, p=0.04) and PS at recurrence (PS1 vs. PS0: HR=2.00, 95% CI=1.08-3.70, p=0.01) was a significant poor prognostic factor for survival after recurrence, and ICIs treatment significantly improved survival after recurrence (HR=0.52, 95% CI=0.30-0.89, p<0.01).

Conclusions: Our results demonstrated that ICIs treatment significantly prolonged survival of postoperative recurrence with wild-type EGFR NSCLC regardless of PD-L1 status, whereas postoperative first distant recurrence and PS at recurrence were associated with poor prognosis.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.11.48 Scoreit - Is IC3 Similarly Predictive as TC3 for Single Agent PD-1/PD-L1 Immune Checkpoint Inhibition in Metastatic NSCLC (mNSCLC)

N. Olejnik[1], J. Roeper[2], M. Tiemann[3], L. Heukamp[3], K. Wedeken[2], A. Blume-Vulin[2], K.C. Willborn[2], F. Griesinger[2]
[1]Carl-von-Ossietzky University, Oldenburg/DE ,[2]Pius Hospital Oldenburg, Oldenburg/DE ,[3]Institut für Hämatopathologie Hamburg, Hamburg/DE

Introduction: The use of immune checkpoint inhibitors (ICI) has led to significant improvements in survival rates in mNSCLC. PD-L1 expression on tumor cells (TC) and immune cells (IC) have been correlated with high response rates, PFS and OS benefit by single agent ICI compared with chemotherapy. However, there are only sparse data on the predictive impact of IC3 (>10% immune cells) with TC<3 (<50% tumor cells) on ICI single agent therapy.

Methods: In a retrospective single center study of the Lungenkrebszentrum Pius-Hospital Oldenburg, 593 NSCLC patients (of all stages) were tested for PD-L1 expression between 2021 and 2023, 269/606 (45%) were identified with high PD-L1 expression and 32% (87/269) of them received PD-1/PD-L1 ICI as palliative first-line monotherapy. The following groups were analyzed: TC3/IC3: 52/269, IC3/TC<3: 76/269 and TC3/IC<3: 141/269 patients. Clinical data including gender, age, smoking status, PD-L1 score and type of ICI therapy were captured. The primary end points were best overall response, overall survival and progression-free survival.

Results: Median age of the 269 patients was 66 years (range 37-88 years), 60% of them were male and 72% were current or ex heavy smoker. In the IC3/TC<3 group, 22 patients were treated with a PD-L1 inhibitor as palliative first-line monotherapy, while 40 patients in the TC3/IC<3 group received a PD-1 inhibitor as monotherapy. Median overall survival was longer in the IC3/TC<3 group with 28.6 months (95% CI: 18.0-39.2 months) versus 13.3 months (95% CI: 2.6-24.0 months) in the TC3/IC<3 group (HR: 0.58; 95% CI: 0.29-1.14], p=0.112). Median PFS was similar in both groups, 8.6 months (95% CI: 2.5-14.6 months) for IC3/TC<3 and 10.1 months (95% CI: 8.3-12.0 months) for TC3/IC<3 (HR: 1.35; 95% CI: 0.67-2.73; p=0.398). Objective response rate was higher for IC3/TC<3 versus TC3/IC<3 (41% vs. 33%; p=0.850).

Conclusions: In metastatic NSCLC, treatment with the PD-L1 inhibitor atezolizumab in patients with PD-L1 expression of IC3/TC<3 led to a descriptively longer OS than treatment with PD-1 inhibitor pembrolizumab or cemiplimab in patients with TC3/IC<3. These data indicate that the predictive value of IC3, irrespective of tumor cell PD-L1 expression, might be similar to TC3. These data will be expanded in a larger prospective registry cohort.

Introduction: While immune checkpoint inhibitors (ICIs) have revolutionised cancer management, their success has been tempered by immune related adverse events (IrAEs). Checkpoint inhibitor pneumonitis (CIP) is the most common cause of IrAE associated mortality and poses a significant clinical challenge. While there has been extensive research evaluating the impact of the gut microbiome on lung cancer treatment and complications, the impact of the lung microbiome remains a relative unknown. In this study, we aim to characterise the complex microbial - immune microenvironment that drives CIP and look for potential biomarkers and treatment targets in this vulnerable patient population.

Methods: Through the TRACKER lung cancer biobank, an Australian based lung cancer biospecimen repository, bronchial alveolar lavage fluid (BALF) samples were acquired in CIP cases and non-CIP controls. Each BALF sample had matched blank, scope, and oral fluid controls. Following collection, DNA was extracted from samples and sent for 16S rRNA microbial profiling via the Illumina NextSeq™ 2000 platform.

Results: In total, 10 patients (27 samples), comprising 2 CIP and 8 non-CIP patients were included in this initial pilot analysis. Firmicutes, Proteobacteria and Bacteriodota were the most abundant phyla, while Streptococcus (29%), Veillonella (6%) and Gemella (3%) genera demonstrated the highest relative abundance across the samples (Figure1). While relative abundance in Firmicutes, Proteobacteria and Bacteriodiota were similar between CIP and non-CIP cohorts, there was increased relative abundance of Acidobacteriota and Planctomycetota in the CIP cohort (Figure2).

Conclusions: Preliminary results from this small biobank based study demonstrates characteristics of the lung microbiome in patients with CIP. Further analysis on a larger sample cohorts will be conducted to explore the impact of lung microbiome composition on inflammatory responses driving CIP.

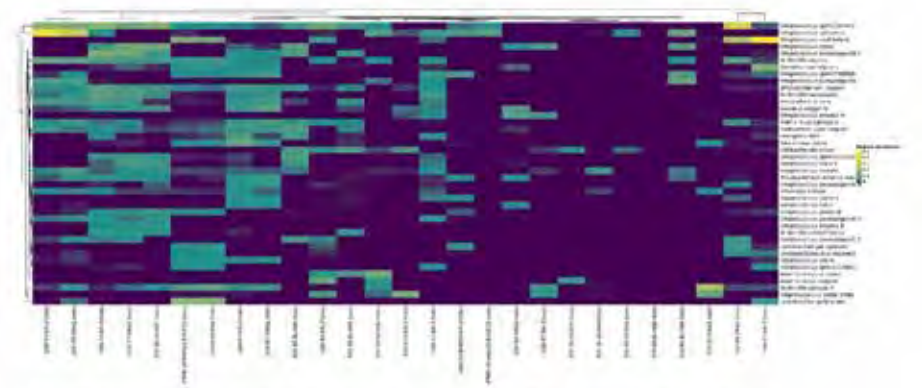

Figure 1: Heatmap depicting phylogenetic distribution across samples. Only species with >1% abundance in at least 2 samples for the top 10 genus were including in this heat map.

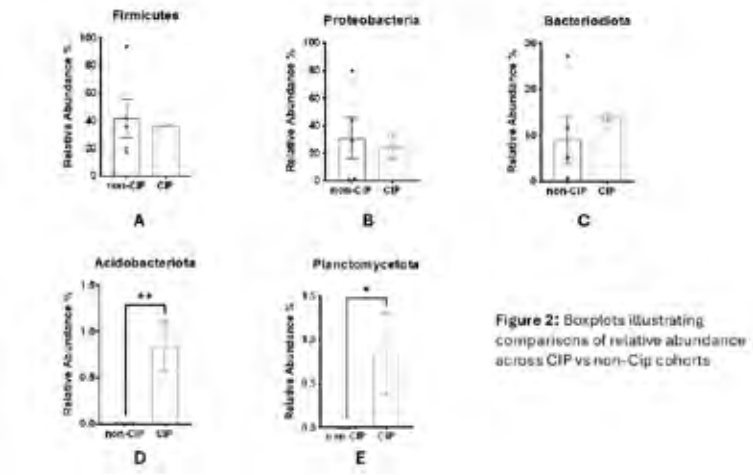

Figure 2: Boxplots illustrating comparisons of relative abundance across CIP vs non-Cip cohorts

P1.11.50 Survival Outcomes in Advanced Pulmonary Sarcomatoid Carcinoma Treated With Immunotherapy: An NCDB Analysis

U. Karki[1], P. Budathoki[2], S. Gaire[3], M. Agarwal[1], N. Pokharel[4], C. Kim[1]
[1]MedStar Georgetown University Hospital, Washington/DC/USA ,[2]H. Lee Moffit Cancer Center and Research Institute, Tampa/FL/USA ,[3]Mount Sinai Hospital, Chicago/IL/USA ,[4]St Francis Medical Center, Monroe/LA/USA

Introduction: Pulmonary sarcomatoid carcinoma (PSC) is a rare and aggressive type of non-small cell lung cancer (NSCLC), associated with poor prognosis and resistant to standard platinum-based chemotherapy. Owing to its rarity, survival outcomes in advanced-stage PSC treated with immunotherapy, either alone or in combination with chemotherapy, remain understudied, particularly in comparison to other NSCLCs.

Methods: Demographics, treatment, and survival data for stage IV NSCLC, including PSC, diagnosed between 2015 and 2020 were extracted from NCDB. Univariate survival analysis was conducted using the log-rank test, and Cox multivariate regression was employed to adjust for confounding factors, including age, gender, race, comorbidities, insurance, and treatment facility (academic or community).

Results: A total of 292,751 patients were identified, including 1,039 PSCs and 291,712 other NSCLCs. Of the 515 PSCs that received systemic therapy as the first course of treatment, 229 (44%) received chemotherapy alone, 142 (28%) received immunotherapy alone and 144 (28%) received chemoimmunotherapy. PSC treated with chemotherapy alone had significantly shorter survival than those treated with immunotherapy alone (median overall survival [OS] 6.2 vs 9.7 months, HR 0.82, 95% CI 0.80 - 0.84, p = 0.01) or chemoimmunotherapy (median OS 6.2 vs 12 months, HR 0.83, 95% CI 0.82 - 0.85, p <0.001). Although chemoimmunotherapy was associated with numerically longer survival than immunotherapy alone (median OS 12 vs 9.7 months), the difference was not statistically significant (HR 0.93, 95% CI 0.67 - 1.3, p = 0.3). Among PSC subtypes, spindle cell PSCs demonstrated a survival benefit from immunotherapy compared to chemotherapy (HR: 0.32; 95% CI: 0.15-0.7, p = 0.003), whereas pleomorphic PSCs showed no significant difference (HR: 1; 95% CI: 0.46-2.11, p = 0.8). Compared with other NSCLCs, PSC had significantly shorter survival when treated with chemotherapy alone (median survival 6.2 vs 10.6 months, p <0.001, HR 0.67, 95% CI 0.57 - 0.79). However, no difference in survival was observed between PSC and other NSCLC when treated with immunotherapy alone (median OS 9.7 months vs 11.5 months, HR 0.78, 95% CI 0.56 - 1.11, p = 0.07) or with chemoimmunotherapy (median OS 12 vs 12.9 months, HR 0.87, 95% CI 0.61 - 1.24, p = 0.4).

Conclusions: This study demonstrates that patients with PSC treated with immunotherapy-based treatment achieve better survival outcomes than those treated with chemotherapy alone, with the spindle cell subtype appearing to benefit the most. In the era of immunotherapy, PSC is no longer associated with worse survival outcomes compared to other NSCLC subtypes. Future studies should incorporate biomarkers such as PD-L1 expression and driver mutation status, and evaluate chemotherapy partners in chemoimmunotherapy to better understand treatment response and optimize therapeutic strategies.

P1.11.51 Effects of Immune Checkpoint Inhibitors on the Pulmonary Circulation in Lung Cancer Patients

X. Yang, L. Wang, Y. Xu, h.Q. Zhang, T. He, M. Zhang, H. Shan, J. Shi, B. Yuan
The Second Affiliated Hospital of Xi'an Jiaotong University, Xi 'an/CN

Introduction: This paper aims to investigate whether ICIs lead to dysfunction of the pulmonary circulation system, to assess the utility of the PAD/AoD as a prognostic predictor, and to discuss related risk factors.

Methods: This retrospective cohort study investigated 461 lung cancer patients treated with ICIs over two years, analyzing changes in pulmonary artery diameter (PAD), aortic diameter (AoD), and the pulmonary artery/aortic diameter (PAD/AoD) ratio through chest computed tomography (CT) at baseline, 3 months, 6 months, 1 year, and 2 years post-treatment, and collecting clinical data to identify risk factors.

Results: The PAD from 25.19 mm to 26.33 mm ($p < 0.001$) and the PAD/AoD ratio from 0.70 to 0.73 ($p < 0.001$) during ICI treatment over a 2-year follow-up period, as early as within the first three months. High-sensitivity troponin I (hs-TnI), α-hydroxybutyrate dehydrogenase (HBDH), creatine kinase (CK), creatine kinase MB (CK-MB), and coagulation indices exhibited significant changes ($p < 0.05$), while cardiac ultrasound result remained unchanged. In subgroup analysis, the severe group demonstrated lower progression-free survival (PFS) (9 months vs. 16 months, $p < 0.001$), overall response rate (ORR) (3.5% vs. 9.1%, $p = 0.004$), and disease control rate (DCR) (48.7% vs. 59.8%, $p = 0.022$) compared to the non-severe group. Meanwhile, the severe PAD/AoD ratio progression(HR 2.144 [95% CI 1.580-2.911] $p<0.001$)and ICI treatment cycle(HR 0.521 [95% CI 0.379-0.717] $p<0.001$)serve as independent predictors of PFS, but immune-related pneumonia(CIP) did not significantly influence the PAD/AoD ratio progression ($p >0.999$).

Conclusions: In lung cancer patients treated with ICIs, pulmonary vascular involvement can occur within the initial three months. Furthermore, severe PAD/AoD ratio progression is a risk factor for PFS, while ICI treatment cycles confer a protective effect on PFS.

P1.11.52 Impact of Disease Progression on Pros in Patients Receiving Cemiplimab/Chemotherapy Versus Chemotherapy for aNSCLC: EMPOWER-Lung 3 Part 2

K. Penkov[1], A. Baramidze[2], T. Makharadze[3], M. Gogishvili[4], T. Melkadze[5], X. Jia[6], E. Kim[6], E. Yan[7], R.G.W. Quek[6]
[1]Private Medical Institution Euromedservice, St Petersburg/RU ,[2]Todua Clinic, Tbilisi/GE ,[3]LTD High Technology Hospital Med Center, Batumi/GE ,[4]High Technology Medical Centre, University Clinic, Tbilisi/GE ,[5]Acad F Todua Medical Center, Tbilisi/GE ,[6]Regeneron Pharmaceuticals, Inc., Tarrytown/NY/USA ,[7]Cyan Global Inc., San Diego/CA/USA

Introduction: EMPOWER-Lung 3 part 2 (NCT03409614), a double-blind, placebo-controlled phase 3 study, investigated first-line cemiplimab (anti-programmed cell death 1 [PD-1]) plus chemotherapy versus placebo plus chemotherapy in patients with advanced non-small cell lung cancer (aNSCLC). Clinically meaningful and statistically significant improvements in overall survival (OS) and progression-free survival (PFS) were observed with cemiplimab plus chemotherapy (n=312) versus chemotherapy alone (n=154) (OS: HR 0.65; 95% CI 0.51-0.82; P=0.0003; PFS: HR 0.55; 95% CI 0.44-0.68; P<0.0001). The safety profile was consistent with the previously reported profile for cemiplimab and other PD-1 or programmed cell death-ligand 1 inhibitors in aNSCLC and other tumour types. To evaluate the effects of disease progression on patient-reported outcomes (PROs), we performed post-hoc analyses of patients with and without disease progression, based on both treatment arms combined and for each treatment arm separately.

Methods: PROs were assessed at baseline and Day 1 of each treatment cycle for the first 6 cycles, and then on Day 1 of every third cycle using the European Organisation for Research and Treatment of Cancer Quality of Life-Core 30 (QLQ-C30) and Lung Cancer Module questionnaires. The focus of this post-hoc analysis was the QLQ-C30 global health status (GHS)/quality of life (QoL) scale, with higher scores indicating better outcomes. Patients were grouped by their Response Evaluation Criteria in Solid Tumors-based disease progression status (with vs without disease progression) within each treatment arm. Repeated measures mixed-effects analyses were performed to compare overall change from baseline scores while controlling for baseline. Disease progression status at each time point was included as a covariate. Time to onset of definitive clinically meaningful deterioration (TTD) (decrease of ≥10 points) in GHS/QoL was compared between patients with versus those without disease progression using a stratified Cox proportional hazards model with disease progression status included as a time-dependent covariate.

Results: In all patients in the study (both treatment and control arms), an overall change from baseline in GHS/QoL scores significantly favoured patients without disease progression versus those with disease progression (difference in least squares [LS] means: 4.65; 95% CI 2.31-6.99). Similarly, an overall change in GHS/QoL scores significantly favoured patients without disease progression in the cemiplimab plus chemotherapy arm (difference in LS means: 3.97; 95% CI 1.09-6.85) and in the chemotherapy-alone (difference in LS means: 7.61; 95% CI 3.28-11.95) arm, separately. Additionally, in all study patients, a significantly greater delay in TTD in GHS/QoL was observed in patients without versus with disease progression (HR 0.37; 95% CI 0.20-0.68). Similarly, a significantly greater delay in TTD in patients without versus with disease progression was also seen in the cemiplimab plus chemotherapy arm (HR 0.40; 95% CI 0.18-0.87) and in the chemotherapy-alone (HR 0.39; 95% CI 0.13-1.15) arm, separately.

Conclusions: In patients with aNSCLC, overall change from baseline and TTD in GHS/QoL significantly favoured patients without disease progression versus those with disease progression. These results suggest that an increase in PFS may lead to a more favourable overall change from baseline and a greater delay in TTD in GHS/QoL among patients with aNSCLC.

P1.11.53 Organ-Specific Survival in Metastatic NSCLC Patients Treated With Chemo-Immunotherapy: A Machine Learning-Based Retrospective Analysis

K. Qin[1], A.A. Qin[2], J.V. Heymach[3]
[1]MDanderson, Houston/TX/USA ,[2]Rutgers University, Newark/NJ/USA ,[3]University of Texas MD anderson cancer center, Houston/TX/USA

Introduction: Currently, organ-specific progression-free survival (PFS) and overall survival (OS) in patients with metastatic non-small cell lung cancer (NSCLC) treated with chemo-immunotherapy have not been comprehensively elucidated. This study aimed to evaluate organ-specific metastatic progression patterns, investigate associated survival outcomes, and develop machine learning models to predict prognosis in metastatic NSCLC patients.

Methods: We included NSCLC patients treated with systemic chemo-immunotherapy at MD Anderson Cancer Center between January 2009 and January 2025. Demographic and clinical features, including age, gender, histology, baseline metastatic sites, genomic alterations, prior treatment history, and site of first progression, were collected. Kaplan-Meier analysis was used to compare PFS and OS across progression sites. LASSO-Cox proportional hazards regression was used to identify independent prognostic factors. Real-world PFS and OS were primary outcomes for this study. Disease progression was determined based on pathologic confirmation or clinical progression determined by the treating physician based on imaging reports or through clinical assessment. Twelve machine learning models—including Multilayer Perceptron (MLP), Gradient Boosted Trees (GBT), Random Forest, SVM, Logistic Regression, Naive Bayes, CatBoost, AdaBoost, Bagging, ExtraTrees, LightGBM, and Decision Tree—were trained and evaluated to predict disease progression and mortality. Model performance was assessed using ROC curves, precision-recall curves, calibration plots, and decision curve analysis. SHAP (SHapley Additive exPlanations) was used for model interpretation. Analyses were conducted using GraphPad Prism (v10.1.2), R (v4.0.5), and Python (v3.14).

Results: As of the data-lock date (January 31, 2025), 7,049 NSCLC patients treated with immunotherapy were identified. After excluding 2,717 patients due to positive driver mutations or early-stage treatment, 4,332 stage IV NSCLC patients without targetable mutations were included. Among them, 2,634 (60.8%) progressed at the primary tumor, 1,101 (25.4%) in the lung, 696 (16.1%) in the brain, 630 (14.5%) in the liver, 1,296 (29.9%) in the bone, and 549 (12.7%) in the adrenal glands.PFS and OS were significantly shorter in patients who got liver progression than those who had progression in other sites. median PFS (5.07m, 95%CI 4.60m-6.70m), median OS (11.80m, 95%CI 9.90m-14.53m) (P<0.001). PFS and OS of patients who had progression liver metastases, bone metastases were significantly shorter than those who had no progression at liver metastases(mPFS, 5.07m vs 10.47m, P<0.0001; mOS11.80m vs 27.33m, P<0.0001) and bone metastases(mPFS, 7.77m vs 10.43m, P<0.0001; mOS 17.97m vs 26.03m, P<0.0001), respectively.Among all 12 models, the ExtraTrees algorithm showed the best performance in predicting both disease progression(AUC = 0.935, 95% CI: 0.888-0.971) and mortality (AUC=0.995,95%CI 0.937-0.970). Top SHAP predictors of progression: adrenal metastasis, pathology, age, bone metastasis, and N stage. Top SHAP predictors of mortality: PD-L1 expression, age, line of therapy, non-targetable EGFR mutations, and pulmonary metastases.

Conclusions: In metastatic NSCLC patients receiving chemo-immunotherapy, progression patterns differ significantly by organ site and are closely associated with clinical outcomes. Patients with progression in the liver exhibit the shortest PFS and OS. We also developed novel explainable machine learning models that accurately predict disease progression and mortality, which may aid clinicians in personalizing treatment strategies for advanced NSCLC.

Introduction: Treatment of advanced Non-Small Cell Lung cancer (NSCLC) with immune checkpoint inhibitors (ICIs) leads to long-lasting responses in only 20% of patients. Conversely, 14-37% of patients experience rapid disease progression following ICI therapy. Efforts to investigate the causes of fast tumor progression by dissecting the tumor microenvironment at baseline did not yield any clear clinical biomarkers. Further, real-life longitudinal studies focusing on circulating immune components remain limited, and no specific indexes have been established for clinical monitoring. Previously, we demonstrated that low IFN-γ doses modulate NSCLC plasticity associated with ICI-mediated hyperprogression. However, few is known about the regulation of IFN-γ production by T cells. The goal of this study was to investigate the ability of circulating T cells from advanced NSCLC patients to be stimulated and to produce IFN-γ, comparing long-responder with fast-progressor ICI-treated patients.

Methods: Advanced NSCLC patients undergoing ICIs were enrolled and categorized into patients who responded after 1 year of treatment (long responders-LR) and patients who progressed within the first 3 months (fast progressors-FP). Consecutive blood samples of LR were monitored over time to minimize inter-sample variability and record changes associated to progression. Classical, intermediate, and non-classical monocyte subsets were identified using CD14-PE and CD16-FITC. HLA-DR-APC staining was used to assess antigen presentation capacity. PBMCs isolated from FP and LR patients were cultured with ImmunocultTM medium and hu-IL-2 and stimulated with anti-CD3/CD28/CD2 antibodies. Then, intracellular IFN-gamma level was measured. Plasma soluble factors were measured through human Luminex Discovery Assay.

Results: The expression of HLA-DR resulted lower in classical monocytes compared to intermediate and non-classical counterparts. Notably, FP patients had a more than 50% reduction in HLA-DR expression on intermediate monocytes compared to LR patients. This decrease was also observed in LR patients who later experienced sudden disease progression. Pentraxin PTX3, which can inhibit HLA-DR expression, enhance TGF-β production, and bind CD44, was found to be significantly increased in FP compared to LR patients.LR-derived CD4+ T and CD8+ T cells showed a 2-fold increase in IFN-γ production after three days of stimulation with anti-CD3/CD28/CD2 antibodies, compared to FP T cells. Prolonged exposure to immune stimulators further increased IFN-γ secretion by FP T cells but did not in LR ones. Treatment with nivolumab reduced FP CD4-mediated IFN-γ production, while LR T cells showed increased IFN-γ release under nivolumab treatment. Surprisingly, circulating T regulatory cells resulted slightly higher in LR compared to FP patients. This could indicate a lower intratumor Treg localization in the former. Tregs mainly modulate the immune response through IL-10 and TGF-β1 cytokines. We found a 3-fold increase of TGF-β1 in FP respect to LR, while IL-10 was low or undetectable in both groups.

Conclusions: Advanced NSCLC patients receiving ICI therapy showed longer-lasting therapeutic responses in presence of circulating intermediate monocytes with higher HLA-DR expression. Conversely, elevated PTX3—capable of inhibiting antigen presentation and promoting cancer cell plasticity—was found in FP patients. Despite a slower activation profile, T lymphocytes from FP patients retained the capacity to produce IFN-γ.

P1.11.55 Identifying Patients Cured From Metastatic Non-Small Cell Lung Cancer (mNSCLC) With Anti-PD-(L)1 Therapy

D. Boiarsky[1], L. Hong[2], A. Cooper[3], B. Ricciuti[4], L. Spurr[5], M. Saad[2], A. Elkrief[6], A.D. Federico[4], M. Aminu[2], W. Rinsurongkawong[2], J. Lewis[2], D. Gibbons[2], A. Vaporciyan[2], X. Le[2], J.J. Lee[2], J. Heymach[2], J. Wu[2], S.P. Pitroda[5], M. Awad[3], A. Schoenfeld[3], J. Zhang[2], N. Vokes[2]
[1]Yale New Haven Hospital, New Haven/CT/USA ,[2]University of Texas MD Anderson Cancer Center, Houson/TX/USA ,[3]Memorial Sloan Kettering Cancer Center, New York City/NY/USA ,[4]Dana-Farber Cancer Institute, Boston/MA/USA ,[5]University of Chicago, Chicago/IL/USA ,[6]University of Montreal, Montreal/QC/CA

Introduction: Anti-PD-(L)1 therapy can cure patients with advanced cancer, but cure rates remain low in mNSCLC. Identifying patients who are likely to achieve a long-term response could help optimize treatment selection, duration, and surveillance strategies.

Methods: Patients treated with anti-PD-(L)1 therapy across 10 academic institutions and as part of 3 clinical trials were identified. A mixture cure model with a Weibull distribution was used to estimate the cure rate among patients with previously untreated mNSCLC who received anti-PD-(L)1 alone (ICI-mono) or in combination with anti-CTLA-4 therapy (dual-ICI). Unlike the Kaplan-Meier method which assumes all patients may eventually experience the event, a mixture cure model estimates survival by accounting for a cured subgroup that will never experience the event and a non-cured subgroup that follows a traditional survival distribution. Among patients treated across all lines of therapy, pathologic and genomic features were compared between those censored after 3 years of response (considered “possibly cured”), those who progressed after initially responding (acquired-resistance), and non-responders. RECIST v1.1 criteria were used to distinguish between responders and non-responders. Tumor mutational burden (TMB) was z-scored within patients sequenced on the same platform to allow for cross platform comparisons.

Results: A total of 3197 patients were identified, of which 2837 received ICI-mono and 360 received dual-ICI therapy. Estimated cure rates were 11% (95% CI: 8-14%) and 20% (14-26%) among patients treated with front-line ICI-mono (n=912; median PD-L1: 70%, median duration of follow-up: 38 months) and dual-ICI (n=289; 10%; 28 mo). Five year median PFS rates were similar at 11% and 18% respectively. Estimated cure rates were 23% (15-31%), and 43% (31-55%) among responders to front-line ICI-mono (n=280) and dual-ICI (n=114) respectively. There was a significantly higher proportion of complete responders who were “possibly cured” when treated with dual-ICI than with ICI mono (90% vs. 33%, p=0.0011), but no difference in “possible cure” rates between partial responders. There was no difference in PD-L1 expression between “possibly cured” vs. acquired-resistance patients, but there was a significant difference between acquired-resistance patients vs non-responders (ICI-mono: median PD-L1 60% vs. 5%, p=7.2x10-20; dual-ICI: 25% vs. 1%, p=3.9x10-6). Z-scored TMB was significantly higher in “possibly cured” vs acquired-resistance patients, with a larger difference seen in patients treated with dual-ICI (ICI-mono: median z-score: 0.39 vs. 0.15, p=0.0011; dual-ICI: median z-score: 1.2 vs. -0.17, p=0.00064). There was no difference in TMB between dual-ICI treated patients with acquired-resistance vs non-response, whereas a small difference was seen in ICI-mono treated patients. Alterations in FLT4 (VEGFR3) were highly enriched between “possibly cured” patients vs. those who developed acquired resistance to ICI-mono or dual-ICI (odds-ratio=4.3, p=0.0023).

Conclusions: Dual-ICI therapy was associated with a greater proportion of possibly cured patients as compared to ICI-mono in mNSCLC. Higher TMB, particularly in dual-ICI-treated patients, correlated with a greater likelihood of cure. Higher PD-L1, particularly in ICI-mono treated patients, correlated with a greater likelihood of initial response. FLT4 alterations emerged as a potential biomarker of cure, suggesting that lymphangiogenesis may contribute to sustaining immune responses.

Introduction: PD-L1 tumor proportion score (TPS) is a key biomarker for immune checkpoint inhibitors (ICIs) efficacy in non-small cell lung cancer (NSCLC). However, its predictive role in squamous (SQ) histology remains unclear, warranting histology-specific investigation.

Methods: Clinicopathologic, genomic, and outcomes data were collected from patients with advanced NSCLC treated with ICIs ± chemotherapy across five international academic centers. Cox regression assessed the association between PD-L1 TPS and survival outcomes to ICIs by histology, adjusting for treatment regimen and line, while spline-based model explored potential non-linear effect across histologic subtypes. Multiplexed immunofluorescence (mIF) on baseline samples quantified immune cell densities, stratifying by PD-L1 TPS and histology. Mutation enrichment analysis explored genomic correlates of response to ICIs ± chemotherapy in SQ NSCLCs.

Results: Among 5148 patients with NSCLC treated with ICIs ± chemotherapy, 909 (17.7%) had SQ histology. Among patients with available PD-L1 TPS, 37.2% had TPS <1%, 30.1% 1-49%, and 32.7% ≥50%. Increasing PD-L1 TPS categories (<1%, 1-49%, ≥50%) were associated with significant stepwise improvements in progression-free (PFS) and overall survival (OS) in NonSQ but not in SQ NSCLCs (Figure 1A). In SQ, only a dichotomized PD-L1 TPS (<1% vs ≥1%) was predictive of longer PFS (adjusted hazard ratio [aHR]: 0.75, p<0.01) and OS (aHR: 0.78, p=0.02), while no difference was observed between TPS 1-49% and ≥50%. Comparing histologies, survival outcomes were similar in TPS subgroups of <1% and 1-49%, but significantly longer in NonSQ vs SQ among patients with TPS ≥50% (PFS aHR: 1.25, p=0.01; OS aHR: 1.50, p<0.01). Spline-based Cox models confirmed the stepwise association between increasing PD-L1 levels and improved survival in NonSQ NSCLCs, but showed a non-linear, plateauing effect beyond 1% in SQ, with no incremental survival benefit (Figure 1B-E). mIF analysis (229 samples: 22 SQ, 207 NonSQ) revealed lower intratumoral CD8+, PD1+, CD8+/PD1+, and FOXP3+ densities in SQ vs NonSQ NSCLCs. Increasing PD-L1 TPS significantly correlated with higher CD8+ infiltration in NonSQ (R=0.25, p<0.01), but not in SQ (R=-0.034, p=0.89), with similar trends across the other markers. In SQ subgroup, KMT2D, MAP3K1 and FANCA mutations were among the genes enriched in responders to ICIs ± chemotherapy (p<0.05).

Conclusions: Increasing PD-L1 levels show stepwise PFS and OS improvements in NonSQ but not in SQ NSCLCs, where TPS acts as a dichotomous (<1% vs ≥1%) rather than continuous predictor. Distinct immunophenotypic and genomic features confirmed this divergence, warranting histology-specific trials and biomarker strategies.

P1.11.57 Association Between CD274 (PD-L1) Gene Expression and PD-L1 Immunohistochemistry in Non-Small Cell Lung Cancer Specimens

M.L. Cheng[1], D.C. Pavlick[2], R.S.p. Huang[2], R.B. Keller-Evans[2]
[1]University Of California, San Francisco, San Francisco/CA/USA ,[2]Foundation Medicine, Inc., Cambridge/MA/USA

Introduction: The number of immunohistochemistry (IHC)-based biomarkers being developed and validated to guide patient selection for oncology therapeutics is rapidly increasing. However, tumor tissue available for biomarker testing in clinical care is often limited. Multiplex RNA gene expression (GE) for a panel of IHC biomarkers could serve as a screening method, or even a surrogate, for a series of individual IHC tests. As proof of principle, we explored the correlation between CD274 (PD-L1) GE and PD-L1 IHC in non-small cell lung cancer (NSCLC) tissue specimens.

Methods: We queried an institutional database (Foundation Medicine, Inc., Cambridge, MA, USA) of RNA GE and matched PD-L1 IHC results from testing performed from May-September 2024. DNA and RNA co-extracted from FFPE samples were profiled, respectively, using FoundationOne CDx and FoundationOne RNA. PD-L1 IHC was performed with the Dako PD-L1 22C3 PharmDx assay and reported using Tumor Proportion Score (TPS). CD274 (encoding PD-L1) GE (Research Use Only) was quantified from RNAseq data and reported as normalized transcripts per million (TPM).

Results: We identified a cohort of 295 patients diagnosed with NSCLC with available RNA GE and PD-L1 IHC results (TPS 0 = 35.6% [N=105], TPS 1-49 = 36.9% [N=109], TPS ≥50 = 27.5% [N=81]). Three patients had CD274 amplification, all of whom had PD-L1 TPS ≥50; no other pathogenic CD274 alterations were detected. PD-L1 TPS and CD274 expression were positively correlated (Spearman's R = 0.7285, P < .001) and limiting to samples with ≥25% (n=205) or ≥50% (n=96) tumor purity (%TP) strengthened this correlation (R = 0.7485 and R = 0.8022, respectively; P < .001 for both). CD274 expression median [IQR] for clinically relevant TPS thresholds were: TPS 0 58.5 TPM [IQR: 37.2, 98.1]; TPS 1-49 112.1 TPM [IQR: 69.4, 153.8]; and TPS ≥50 276.9 TPM [IQR: 183.6, 399.4] where P < .001 for comparisons across and between all groups. Notably, the IQRs for TPS 0 and TPS ≥50 did not overlap. Moreover, the median difference of expression between TPS 0 and TPS ≥50 further increased when limiting to samples with high %TP: entire cohort (range 5-94% TP) = 218.4; ≥25% TP = 244.3; ≥50% TP = 281.1.

Conclusions: Exploratory analysis demonstrated a positive correlation between CD274 (PD-L1) GE and PD-L1 IHC TPS score, with distinct separation in GE ranges between TPS 0 and TPS ≥50. In the absence of PD-L1 IHC, CD274 GE may be useful to identify NSCLC clinical treatment groups for anti-PD-(L)1 combinations with cytotoxic chemotherapy (TPS 0) versus anti-PD-(L)1 immune checkpoint blockade alone (TPS ≥50). While further clinical correlation is necessary, this serves as a proof of principle for GE as a surrogate for IHC biomarkers. Future investigation is needed to identify clinically relevant expression thresholds for CD274 (PD-L1) for anti-PD-(L)1 immune checkpoint blockade, as well as to explore additional expression biomarkers for antibody-drug conjugates (ADCs) and other novel agents.

P1.11.58 Efficacy of First-Line Treatment in Driver-Negative Non-Small Cell Lung Cancer With Liver Metastases : A Bayesian Network Meta-Analysis

L. Zhang, W. Wu, X. Qu
The First Hospital of China Medical University, Shenyang/CN

Introduction: This study is designed investigate and determine the optimal first-line treatment options for driver-negative non-small cell lung cancer (NSCLC), and to establish a theoretical foundation for making clinical treatment decisions.

Methods: The present study was prospectively registered within the International Prospective Register of Systematic Reviews (PROSPERO; CRD42025632364). A comprehensive search strategy was employed, encompassing major oncology conferences, Embase, the Cochrane Library, Web of Science, and PubMed. The inclusion criteria for the selected studies were Phase III randomized controlled trials (RCTs) with subjects who had liver metastases from driver gene-negative non-small cell lung cancer (NSCLC). The intervention group received PD-1/PD-L1 inhibitor-based treatment or combination anti-angiogenic therapy, while the control group received chemotherapy only. The primary outcome measure was progression-free survival (PFS), and the secondary outcome measure was overall survival (OS). The Bayesian network meta-analysis was conducted using the “gemtc” and “rjags” packages in R 4.2.3 software.

Results: This meta-analysis incorporates data from fifteen clinical trials and 1237 patients. The employment of a PD-1 inhibitor in conjunction with chemotherapy demonstrated a more substantial benefit in terms of both progression-free survival (hazard ratio [HR] = 0.57) and overall survival (HR = 0.68). Furthermore, the PD-1 inhibitor in combination with chemotherapy demonstrated a more favorable outcome in both non-squamous NSCLC (HR=0.37) and squamous NSCLC (HR=0.58). Among the 11 treatment strategies evaluated, the surface under the cumulative ranking curve of camrelizumab plus chemotherapy was 83.06% for PFS and 96.38% for OS.

Conclusions: In treatment-naive patients with driver-negative NSCLC and liver metastases, the combination of a PD-1 inhibitor and chemotherapy provides greater benefits in terms of PFS and OS compared to chemotherapy alone, and camrelizumab plus chemotherapy may be an optimal treatment regimen.

P1.11.59 Effect of IFNG Expression Levels on Real-World Survival Outcomes in Patients With Metastatic Non-Small Cell Lung Cancer Receiving Immunotherapy

M. Altoe[1], S. Papillon-Cavanagh[2], M. Poi[2], S. Yip[1], T. Oakland[1], M.R. Rossi[1]
[1]ConcertAI LLC, Cambridge/MA/USA ,[2]Caris Life Sciences, Phoenix/AZ/USA

Introduction: Despite advances in immunotherapy for metastatic non-small cell lung cancer (NSCLC), a significant proportion of patients do not respond to immune checkpoint inhibitors (ICIs). Identifying effective prognostic biomarkers that are independent of squamous and nonsquamous histology is critical for optimizing treatment strategies in NSCLC. Interferon gamma (IFNG) has emerged as a potential marker for predicting immunotherapy outcomes due to its role in immune modulation.

Methods: We retrospectively evaluated metastatic NSCLC patients treated with first-line ICIs or ICI plus chemotherapy with an ECOG performance status of 0 or 1 at the time of initial diagnosis. Patients were identified from the ConcertAI linked with Caris Life Sciences data, a U.S.-based, de-identified, patient-level dataset that integrates EHR-based clinical data with exomic, transcriptomic, and whole slide imaging data. Patients were grouped based on high and low IFNG expression, defined as the top and bottom quartiles of expression (transcripts per million, TPM). Survival analyses, including Kaplan-Meier estimates and Cox proportional hazard models, were performed, stratified by histological subtypes of adenocarcinoma (N = 414) and squamous cell carcinoma (N = 147), and by IFNG expression levels.

Results: We evaluated 561 patients who met the selection criteria. High IFNG expression was associated with significantly longer median overall survival (OS), regardless of histological subtype. The median OS for high IFNG expression was 26.7 months in adenocarcinoma (N = 111) and 27.6 months in squamous cell carcinoma (N=38). In contrast, low IFNG expression corresponded to a median OS of 15.1 months in adenocarcinoma (N = 99) and 12.9 months in squamous cell carcinoma (N = 42). Cox regression analysis confirmed that low IFNG expression was significantly associated with higher mortality risk (Hazard Ratio [HR] = 1.8, 95% CI = 1.35-2.4, P < .001). Histological subtype did not independently predict OS (p > 0.05).

Conclusions: High IFNG expression is associated with improved survival outcomes in metastatic NSCLC patients treated with ICIs or ICIs plus chemotherapy as first-line therapy independent of histological subtype. These findings suggest the potential utility of IFNG as a prognostic biomarker to guide therapy decisions in higher-risk NSCLC and tailor treatment strategies in this patient population.

P1.11.60 Interstitial Lung Abnormalities and MUC5B Polymorphism in Immune Checkpoint Inhibitor Pneumonitis

M. Altan, F. Soto, S. Gandhi, N. Vokes, J. Zhang, M.B. Antonoff, G. Shroff, H.T. Tran, J.V. Heymach, A. Sheshadri
MD Anderson Cancer Center, Houston/TX/USA

Introduction: Interstitial lung disease (ILD) is a significant risk factor for both immune checkpoint inhibitor (ICI)-related and radiation-induced pneumonitis. Interstitial lung abnormalities (ILA), observed in 10-12% of smokers, are radiological findings associated with an increased risk for progression to ILD. ILD can lead to chronic lung inflammation and fibrosis, often worsening over time due to aging or smoking. A polymorphism in the promoter region of MUC5B (rs35705950-T) is strongly linked to idiopathic pulmonary fibrosis, the most common idiopathic ILD. In population studies, the presence of this polymorphism—specifically, each copy of the MUC5B (rs35705950-T) variant was associated with a 2.8-fold increase in the odds of lung abnormalities compared to those with other major MUC5B alleles. However, its association with and impact on ICI pneumonitis outcomes remain unclear.

Methods: We conducted a case-control study using two metastatic NSCLC cohorts, consisting of over 700 patients treated with anti-PD-(L)1 therapy with or without anti-CTLA-4. The study included 24 cases of ICI pneumonitis, diagnosed by a multidisciplinary team, and 48 matched controls from the same cohort. Controls were selected based on propensity score matching per age and smoking status and had available pretreatment CT scans ILA assessment. We analyzed single nucleotide polymorphism for MUC5B genotyping to determine the presence of the MUC5B rs35705950-T polymorphism and its correlation for pneumonitis risk. We analyzed the correlation between the maximum pneumonitis grade (per CTCAE), clinical outcome and radiologic resolution patterns (full, partial, or no resolution) in patients with ICI pneumonitis in relation to the MUC5B rs35705950-T polymorphism.

Results: The rs35705950-T polymorphism was associated with an approximately five-fold increased risk of ICI- pneumonitis (OR 4.6, 95% CI 1.5-15.8) ILAs were identified in 47% of ICI- pneumonitis cases versus 15% of controls, conferring a five-fold increase in pneumonitis risk (OR 4.9, 95% CI 1.7-14.6). However, MUC5B (rs35705950-T) polymorphism was not associated with pneumonitis severity, clinical outcome or its likelihood of radiologic resolution.

Conclusions: The rs35705950-T polymorphism and pretreatment CT scan findings of ILA significantly increase the risk of ICI-P in NSCLC but do not seem to affect clinical outcomes of ICI pneumonitis. Further studies are needed to validate these findings across diverse populations and improve predictive models.

P1.11.61 Effects of Probiotic Duration and Type on Immunotherapy Efficacy in Non-Small Cell Lung Cancer With or Without Antibiotics

W. Luo[1], Z-J. Huang[1], S-Q. Mei[2], Z-H. Chen[1], Q-Y. Zhang[3], F. Wang[4], Y. Deng[1], H-Y. Tu[1], J-J. Yang[1], C-R. Xu[1], J-H. Chang[3], Y-L. Wu[1], Q. Zhou[1]
[1]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN ,[2]Department of Radiation Oncology, Key Laboratory of Biological Targeting Diagnosis, Therapy and Rehabilitation of Guangdong Higher Education Institutes, The Fifth Affiliated Hospital, Guangzhou Medical University, Guangzhou/CN ,[3]Department of Medical Oncology, National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital & Shenzhen Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Shenzhen/CN ,[4]Department of Oncology, Peking University Shenzhen Hospital, Shenzhen/CN

Introduction: In non-small cell lung cancer (NSCLC) patients, antibiotics impair immunotherapy efficacy, while probiotics can enhance it. The relationship between the duration of probiotics and the restoration of immunotherapy efficacy compromised by antibiotics, as well as its potential to enhance immunotherapy outcomes in antibiotic-naive patients, remains unclear. Furthermore, more probiotic types and their mechanisms for improving immunotherapy efficacy need to be identified and elucidated.

Methods: This multicenter study enrolled wild-type NSCLC patients. Clinicopathological features were recorded, focusing on antibiotic and probiotic use and duration. Baseline fecal and blood samples were collected. Gut microbiota were analyzed via 16S rRNA sequencing, and serum metabolites were analyzed through untargeted metabolomics. Flow cytometry was used to explore potential mechanisms.

Results: 524 wild-type NSCLC patients were enrolled in the study, with fecal samples collected from 22 patients. Patients receiving antibiotics alone exhibited poorer PFS and OS. For those receiving antibiotics, the use of probiotics, regardless of duration, led to improved PFS and OS, which were comparable to those of patients in the No antibiotics + No probiotics group. Among the patients who did not receive antibiotics, those who were treated with probiotics for more than 15 days showed improved PFS. Patients with enriched gut microbiota in un-f-Bifidobacterium and roseburia showed better PFS. The frequency of peripheral Th cells was positively associated with the abundance of un-f-Bifidobacterium. There was also a positive correlation between o-Methoxyphenyl sulfate and the gut microbiota that exhibited better immunotherapy efficacy.

Conclusions: Antibiotics weaken immunotherapy efficacy in wild-type NSCLC patients. Probiotics, regardless of duration, restore this compromised efficacy. For antibiotic-naive patients, taking probiotics over 15 days can improve immunotherapy efficacy. Certain probiotics, including un-f-Bifidobacterium and Roseburia, may be potential candidates for improving the efficacy of immunotherapy.

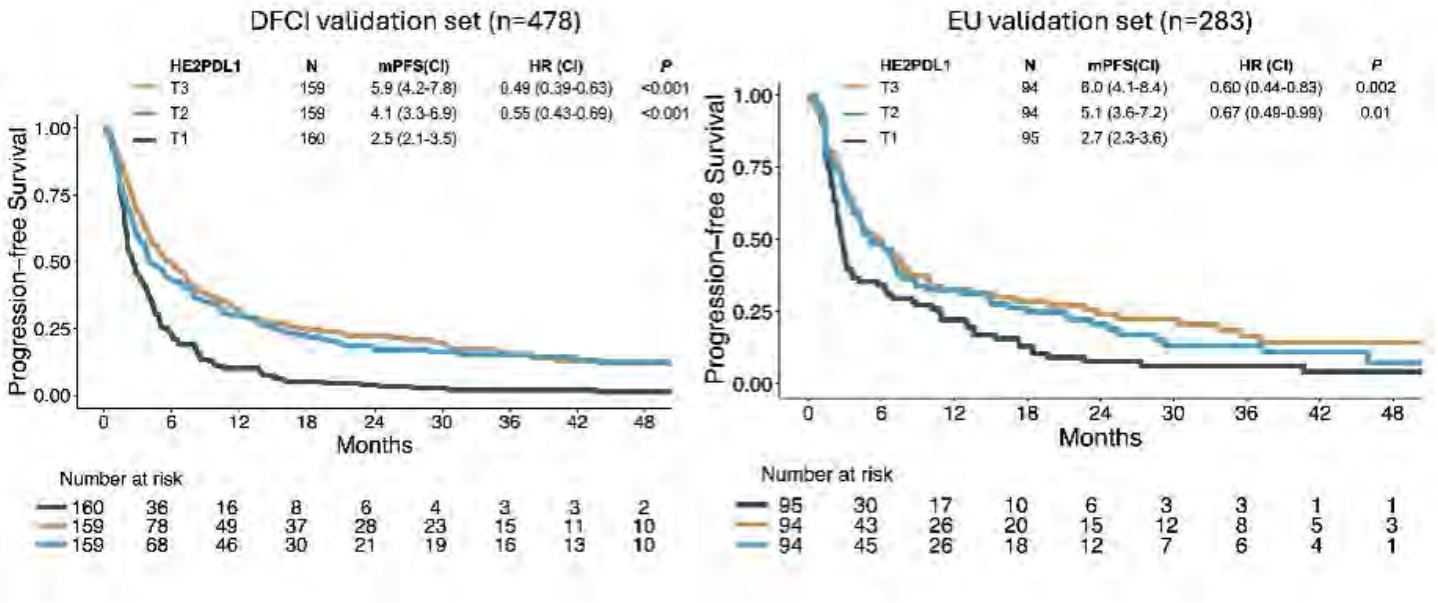
Introduction: PD-L1 expression, assessed by immunohistochemistry (Tumor Proportion Score, TPS), is the key predictive biomarker for managing immunotherapy in advanced lung cancer. We aimed to develop an AI-based model for predicting PD-L1 status directly from H&E images and evaluating its association with immune checkpoint inhibitor (ICI) outcomes.

Methods: We developed a fully automated deep learning model (HE2PDL1) composed of three stages: 1)Tumor detection: A supervised convolutional neural network was trained on 40k H&E image patches (270x270 px) from 624 patients (36% early-stage, 64% late-stage) to identify tumor epithelial regions. 2) Feature extraction of tumor regions was performed using a pathology foundation model (Conch_v1). 3) PD-L1 classification: A transformer-based multi-instance learning model was fine-tuned to classify whole-slide H&E images into three PD-L1 categories (<1%, 1-49%, ≥50%) using immunohistochemistry (TPS) as reference.The model was trained, tuned and evaluated on stage I-IIIA NSCLC patients from the TNM-I trial (NCT03299478; n=720). For external validation, the model was deployed on two independent advanced-stage NSCLC cohorts treated with ICI monotherapy: US cohort (DFCI, n=478) and European multicenter cohort (EU, n=283).

Results: For tumor classification, the model achieved macro F1 score of 0.92 on an external set of 6k images from176 patients (early and late stage). PD-L1 distribution in the overall cohort (n=1481) was: negative 25%, intermediate 32%, and high 43%. In the early-stage development set, the model achieved mean AUC of 0.73 (95% CI: 0.69-0.77) for identifying PD-L1-high tumors in internal 10-fold cross-validation. External validation in two independent cohorts (DFCI and EU) yielded AUCs of 0.75 (0.71-0.80) and 0.67 (0.61-0.73), respectively. HE2PDL1 predictions differentiated ICI objective response with AUCs of 0.69 (0.63-0.73) and 0.60 (0.53-0.66) in the two validation cohorts. A stepwise (tertile-based) increase in HE2PDL1 probability scores was associated with improved progression-free survival following ICI in both external cohorts (Figure), with similar trends observed for overall survival.



Conclusions: The HE2PDL1 deep learning model offers a fast, cost-effective surrogate for PD-L1 IHC testing in NSCLC, using standard H&E slides. It may support treatment decisions when tissue is limited (e.g., small biopsies with no residual material for IHC), staining is inconclusive, or rapid results are needed. Its strong performance across two large independent ICI-treated cohorts suggests value in routine diagnostics.

P1.11.63 Shifts of Mutational Signatures Reveal Response Variability to Pembrolizumab-Based Immunotherapy in NSCLC Patients

M. Nicoś[1], N. Galant[1], N. Krzyzanowska[1], B. Kuznar-Kaminska[2], I. Chmielewska[1], T. Jankowski[1], M. Gil[1], M. Szczyrek[1], R. Kieszko[1], E. Kalinka[3], P. Krawczyk[1], J. Milanowski[1]
[1]Medical University of Lublin, Lublin/PL ,[2]Poznan University of Medical Sciences, Poznan/PL ,[3]Institute of the Polish Mother's Health Center in Lodz, Lodz/PL

Introduction: Immune checkpoint inhibitors, such as pembrolizumab, have revolutionized NSCLC treatment. However, response to immunotherapy remains highly variable and understanding the genomic adaptations is crucial for optimizing the therapy outcomes. In this study, we performed targeted next-generation sequencing (NGS) on tumor (T) and longitudinal liquid biopsy (LB) samples to investigate dynamic mutational changes in NSCLC patients with different responses to pembrolizumab. Analyzing mutational signatures and key driver mutations over follow-up, we aimed to uncover molecular mechanisms associated with durable response or resistance to therapy.

Methods: Within this study, we collected T and LB1 samples before treatment initiation, followed by additional longitudinal LB samples (LB2, LB3, etc.) approximately every 2-3 months during clinical follow-up until therapy completion. Targeted NGS libraries (SureSelect CD Glasgow Cancer Plus Panel, Agilent Technologies, UK) were sequenced on the NovaSeq XPlus system (Illumina, USA) in 2×150 bp read mode. Data preprocessing, including alignment and variant calling, was performed using AGeNT, BWA-MEM, MUTECT2, and VEP, while downstream variant analysis and visualization were conducted using the R package Maftools. This study was funded by the Polish National Centre for Research and Development (LIDER/46/0237/L-12/20/NCBR/2021).

Results: We sequenced 293 samples (77-T, 78-LB1, 55-LB2, 34-LB3, 26-LB4, 23-LB5) from 78 patients (45 males, 33 females; median age: 67±8) treated with pembrolizumab in monotherapy (n=26) or in combination with chemotherapy (n=52) (median PFS: 4 months). Among them, 23 patients were long responders (PFS >12 months), while 55 were short responders (PFS ≤12 months). Mutational analysis showed 70% concordance between T and LB1 samples, with TP53 and KMT2C/D being the most frequently mutated genes in both tissue and liquid biopsy samples. KRAS mutations co-occurring with STK11 (three cases) and KEAP1 (one case) mutations were observed exclusively in short responders. In both T and LB1 samples, short responders showed significant enrichment of the COSMIC_3 signature (associated with HR-related DNA-DSB repair defects), whereas long responders had COSMIC_2 signature (APOBEC), which was significantly associated with TP53 mutations. Over time, both groups transitioned to COSMIC_6 (DNA mismatch repair defects) and COSMIC_30 (unknown etiology) at 3 and 6 months of treatment, respectively. By 12 months (LB4), short responders reverted to COSMIC_3, while long responders retained COSMIC_6 and COSMIC_30, which persisted in LB5. These shifts correlated with the early elimination of TP53 mutations in long responders and their gradual decrease in short responders, as well as the persistence of a KMT2C/DNMT3A-mutated clone, which frequency fluctuated over time.

Conclusions: The dynamic shifts in mutational signatures during treatment reflect ongoing tumor evolution under pembrolizumab pressure, revealing distinct genomic adaptation patterns between long and short responders. Long response was associated with a pre-treatment APOBEC signature and the early elimination of TP53 mutations, potentially supporting the maintenance of adaptive mutational profiles. Conversely, short responders initially exhibited a mutational shift but eventually reverted to their original HR-related DNA-DSB repair defect signature, suggesting an inability to preserve adaptive genomic changes under treatment.

P1.11.64 Vision Foundation Model to Predict Immunotherapy Treatment Response in Lung Cancer Patients

J. Jiang, H. Yu, D. Gomez, H. Veeraraghavan
Memorial Sloan Kettering Cancer Center, New York/NY/USA

Introduction: Immunotherapy is an advanced approach for treating lung cancer patients. Accurately predicting treatment response allow clinicians to better select patients benefitting from treatment. This study developed an artificial intelligence (AI) approach to predict immunotherapy response in patients with stage-III-IV locally-advanced-non-small-cell lung cancer (NSCLC) using large vision foundation model (VFM), integrating longitudinal computed tomography (CT) imaging and tumor mutational burden (TMB) to predict durable clinical benefit (DCB) defined as no progressive disease within 6 months of treatment initiation.

Methods: A transformer based VFM was created using large and diverse 3D-CT sourced from public and institutional datasets using self-supervised learning. The VFM was refined using 10-fold stratified cross validation using 200 patients with NSCLC to predict DCB. A longitudinal AI model using pretreatment CT (pCT) and CT scan acquired 9 weeks as well as pCT AI model were created. Subset of 153 patients with available TMB were combined with the image to create an AI-TMB model. Performance metrics including AUROC, specificity, and sensitivity. Kaplan-Meier survival analysis was performed to evaluate overall-survival (OS) and progression-free survival (PFS).

Results: The longitudinal-AI-model was the most accurate (AUC-0.89±0.07, sensitivity-0.87±0.09, specificity-0.86±0.16) and was associated with PFS ($p < 0.0001$, Harrell's c-index:0.713) and OS ($p < 0.0001$, c-index: 0.703) using uni- and multivariable cox regression shown in Table 1. AI-TMB model was slightly less accurate (AUC: 0.83 ±0.16, sensitivity: 0.83±0.20, specificity:0.83±0.16) and was also associated with PFS ($p = 0.0001$, c-index: 0.63) and OS ($p = 0.0005$, c-index: 0.639). pCT only model was the least accurate. Figure 1 shows the Kaplan-Meier curves computed by dichotomizing patients into low- versus high-risk groups using probability of predicting DCB with a cut-off of 0.5.

Conclusions: VFM could combine longitudinal-CT as well as CT-TMB to accurately predict immunotherapy response. Further analysis on other institutional cohorts is needed to evaluate model generalization capabilities.

Introduction: HARMONi-2 (NCT05499390), a phase 3 randomized trial in China compared ivonescimab, a novel bispecific antibody targeting programmed cell death-1 (PD-1) and vascular endothelial growth factor (VEGF), with pembrolizumab as monotherapy in 398 patients with PD-ligand-1 (PD-L1)-positive (tumor proportion score [TPS] ≥1%) advanced non-small cell lung cancer (NSCLC). In the primary analysis, treatment with ivonescimab resulted in a statistically significant improvement in progression-free survival (PFS) compared with pembrolizumab (hazard ratio [HR] 0.51 [95% CI 0.38-0.69]; one-sided P<0.0001) and PFS was broadly consistent across prespecified subgroups of patients. The objective of this subgroup analysis was to further assess efficacy and safety outcomes by level of tumor PD-L1 expression based on TPS.

Methods: HARMONi-2 was a randomized, double-blind phase 3 trial that enrolled adults with locally advanced or metastatic PD-L1-positive NSCLC without EGFR mutations or ALK translocations and had not received previous systemic therapy. Patients were randomly assigned (1:1) and received intravenous ivonescimab 20 mg/kg or pembrolizumab 200 mg every 3 weeks for up to 24 months; randomization was stratified by PD-L1 TPS expression, histology, and clinical stage. Efficacy and safety endpoints reported in primary analysis of HARMONi-2 were evaluated in this subgroup analysis of patients with PD-L1 TPS 1-49%, TPS ≥50%, and TPS ≥90%.

Results: The ivonescimab treatment group included 115 patients with PD-L1 TPS 1-49%, 83 patients with TPS ≥50%, and 27 patients with PD-L1 TPS ≥90%. The pembrolizumab treatment group included 115 patients with PD-L1 TPS 1-49%, 85 patients with TPS ≥50%, and 28 patients with PD-L1 TPS ≥90%. At the January 29, 2024, data cutoff, median follow-up was 8.7 months. The unstratified HR (95% CI) for PFS was 0.54 (0.37-0.78) in patients with PD-L1 TPS 1-49%, 0.48 (0.29-0.79) in patients with TPS ≥50%, and 0.47 (0.16-1.36) in patients with TPS ≥90%. In the ivonescimab treatment group, the overall response rate (ORR) in patients with TPS 1-49% was 43%, 60% in patients with TPS ≥50%, and 63% in patients with TPS ≥90%. In the pembrolizumab treatment group, the ORR was 31%, 48%, and 64%, respectively. Serious treatment-related adverse events (TRAEs) occurred in 23 (20%) patients in the ivonescimab group versus 13 (11%) patients in the pembrolizumab group in the TPS 1-49% subgroup, 18 (22%) vs 19 (22%) patients in the TPS ≥50% subgroup, and 8 (31%) versus 7 (25%) patients in the TPS ≥90% subgroup. Grade ≥3 hemorrhage AEs were similar in patients in the ivonescimab treatment group: 1 (1%) patient in the TPS 1-49% subgroup, 1 (1%) patient in the TPS ≥50% subgroup, and 1 (4%) patient in the TPS ≥90% subgroup and were similar to the rates seen in patients in the pembrolizumab treatment group: 0 versus 1 (1%) versus 0 patients, respectively.

Conclusions: Although the study was not powered to analyze efficacy by PD-L1 subgroups, this analysis shows overall evidence of numerically better PFS benefit and higher response rate with manageable safety profile for ivonescimab compared to pembrolizumab across all PD-L1 subgroups.

Introduction: Accurately predicting the efficacy of immunotherapy (IO) in individuals with non-small cell lung cancer (NSCLC) remains a key challenge in personalized care. Reliable prognostic tools are critical to support informed decision-making, particularly given IO's potential to offer improved quality of life compared to chemotherapy. Recent advances in machine learning (ML) applied to real-world clinical and laboratory data show promise in enhancing the prediction of IO outcomes and guiding treatment strategies.

Methods: We analyzed data from 1,130 individuals with stage IIIB-IV NSCLC treated with immunotherapy across ten Italian institutions participating in the APOLLO11 study (NCT05550961). Machine learning (ML)-based survival analysis (Cox-ML and other survival models) was used to evaluate overall survival (OS), while classification models (logistic regression and random forest) were developed to predict which patient will have a very poor prognosis (defined as OS<6 months). The dataset was divided into training and internal test sets, with one centre reserved as an external validation set to assess model generalizability. To prioritize the identification of individuals most likely to benefit from IO, we implemented cost-sensitive learning strategies. These adjustments were designed to minimize false negatives ensuring that those with potential benefits would be correctly identified and not excluded from IO treatment. Explainability methods were applied to identify and validate the most influential features across models.

Results: The best classification model achieved an AUC of 0.72 on the test set. On external validation, the model achieved an AUC of 0.80, indicating good generalizability across centres. SHAP analysis highlighted high ECOG performance status, high neutrophil-to-lymphocyte ratio (NLR), and low lymphocyte count as the strongest predictors of very poor prognosis. Models outperformed established biomarker PDL1 (AUC 0.65) and EPSILON score (AUC 0.50) on the test set. For survival prediction, the best-performing model was Cox-ML achieving c-index values of 0.72 and 0.64 on internal test and external validation sets, respectively.

Conclusions: The application of AI methodologies enhanced predictive performance, underscoring the value of RWD, including clinical parameters and laboratory results, and highlighting opportunities for further optimization. Explainability outputs aligned with established prognostic scores such as LIPI and EPSILoN. Given the lack of reliable tools to guide immunotherapy decisions, where choices often rely on subgroup analyses and assumptions, these models show the potential of leveraging routinely collected data to provide practical, scalable decision support in real-world settings through a cost-efficient approach that uses simple ML methods and standard clinical data.

P1.11.67 VEGFR1/PD-L1 CAR-T cell treatment of solid tumor-derived malignant pleural effusion/ascites

D. LI[1], X. He[2], H. Shi[3], Y. Li[4], G. Gao[5], Y. Chen[5], M. Feng[4], B. Zhang[5], N. Liu[4], Y. Wang[4]
[1]Institute of Respiratory Health, State Key Laboratory of Respiratory Health and Multimorbidity, Frontiers Science Center for Disease-related Molecular Network, Sichuan Provincial Engineering Laboratory of Precision Medicine, Precision Medicine Key Laborat, Chengdu/CN ,[2]Division of Thoracic Tumor Multimodality Treatment, Cancer Center, Clinical Trial Center, West China Hospital, Sichuan University/CN ,[3]Division of Thoracic Tumor Multimodality Treatment, Cancer Center, West China Hospital, Sichuan University/CN ,[4]Division of Thoracic Tumor Multimodality Treatment, Cancer Center, Chengdu/CN ,[5]Division of Thoracic Tumor Multimodality Treatment, Cancer Center, Clinical Trial Center, Chengdu/CN

Introduction: Malignant pleuraleffusion/ascites (MPE/MA) is a frequent and disabling complication in patientswith advanced-stage cancers. Previously, we reported that PD-L1 wassignificantly upregulated on tumor and immune cells in MPE/MA, and designed aPD-L1-targetd chimeric switch receptor (PD-L1 CSR), which could enhance thetumor environmental fitness of 2nd generation CAR-T cells. Here, we found that vascular endothelialgrowth receptor 1 (VEGFR1) was broadly and strongly expressed on disseminated tumor cellsin MPE/MA (63 solid tumor patients in total, including 14 lung cancers, 11breast cancers, 6 stomach cancers, and 22 ovarian cancers). This dual targeting rationale promptedthe design of PD-L1 CSR-modified VEGFR1-specific CAR-T cells (VEGFR1/PD-L1CAR-T) to address immunosuppressive and angiogenic tumor microenvironments.

Methods: Preclinicalvalidation demonstrated potent antitumor activity of VEGFR1/PD-L1 CAR-T cellsagainst pleural and abdominal metastatic tumors in murine models. Subsequently,a 3+3 dose escalation, investigator-initiated phase I clinical trial was conducted. Thirteensolid tumor patients with MPE/MA were enrolled, among which six patients (5 NSCLC) were diagnosed with MPE. Patients receivedweight-adjusted infusions of VEGFR1/PD-L1 CAR-T cells, with safety and efficacyoutcomes evaluated.

Results: Treatment achieved 100% MPE control, with transient low-grade fever and mild cytokine elevation as the sole adverse events. The current results supported the potential of VEGFR1/PD-L1 CAR-T as a novel therapeutic for patients with MPE/MA.

Conclusions: These results underscore the feasibility and therapeutic potential of dual-targeted VEGFR1/PD-L1 CAR-T cells for managing MPE/MA, warranting further clinical investigation in advanced solid malignancies.

P1.11.68 Multi-Omic Profiling Identifies Key Factors Associated With Response to Ivonescimab (AK112) in Non-Small Cell Cance

H. Wang[1], Z. Tang[1], C. Zhou[2]
[1]Shanghai Pulmonary Hospital, shanghai/CN ,[2]Shanghai East Hospital, shanghai/CN

Introduction: Monotherapy with immune checkpoint inhibitors has shown limited efficacy in non-small cell lung cancer (NSCLC). Ivonescimab (AK112), a bispecific antibody targeting PD-1 and VEGF, demonstrated promising results in the Phase 3 HARMONi-2 trial. This study aims to identify predictive biomarkers for AK112 efficacy and explore immune escape mechanisms within the tumor microenvironment (TME).

Methods: This retrospective study included 56 NSCLC patients treated with AK112 between May 2021 and July 2024. Blood biomarkers were analyzed for their predictive value, and a model was developed. The TME immune landscape was evaluated using single-cell transcriptomics, TCR sequencing, multiplex immunohistochemistry, and flow cytometry

Results: Biomarkers such as NLR, MLR, PLR, ApoE, and PD-L1 were found to be associated with treatment response. Among these, PD-L1 exhibited the highest predictive accuracy (AUC 0.623). A predictive model incorporating these biomarkers accurately forecasted the objective response rate (ORR) (AUC 0.742) and progression-free survival (PFS) (P = 0.0081). Single-cell RNA analysis revealed differences in immune cell populations, with APOE+ macrophages correlating with better responses. The proximity of immune cells to tumor vasculature was found to influence treatment efficacy. Flow cytometry further confirmed the pivotal role of APOE+ macrophages in the treatment response.

Conclusions: Blood biomarkers effectively predict the outcomes of AK112 treatment in NSCLC. The developed predictive model provides valuable prognostic insight. APOE+ macrophages play a critical role in the drug's efficacy, and TME analysis offers key insights for developing personalized treatment strategies. This study emphasizes the importance of individualized approaches in NSCLC treatment.

P1.11.69 Efficacy of Immunotherapy ± Chemotherapy in Metastatic NSCLC with KRAS, STK11, or KEAP1 Mutations: A Network Meta-Analysis

I. Mamede[1], S. Taylor[2], G. Gazzoni[3], I.J. Piya[4], I.J. Riya[4], C. Stecca[5], G.M.M. Lopes[6], V. Ernani[2]
[1]Federal University of São João del Rei, Divinopolis/BR ,[2]Mayo Clinic Arizona, Phoenix/AZ/USA ,[3]Hospital do Servidor Público do Estado de São Paulo, São Paulo/BR ,[4]Dhaka Medical College and Hospital, Dhaka/BD ,[5]Mackenzie Evangelical University Hospital, Curitiba/BR ,[6]University Centre FMABC, Santo André/BR

Introduction: Mutations in KRAS, STK11, and KEAP1 are associated with poor prognosis in metastatic non-small cell lung cancer (NSCLC), yet optimal treatment strategies for these subgroups remains unclear. This Bayesian network meta-analysis (NMA) comprehensively evaluates the comparative efficacy of PD-1/PD-L1 inhibitors, CTLA-4 inhibitors, and chemotherapy (CT), alone or in combination, in these molecular subgroups of patients.

Methods: We conducted a systematic review and NMA following PRISMA guidelines, including randomized controlled trials from PubMed, Cochrane, Embase, ClinicalTrials.gov, and major conference proceedings up to February 2025. Studies assessed the following first-line systemic therapies in advanced NSCLC with confirmed KRAS, STK11, or KEAP1 mutations: 1) PD-1/PD-L1 inhibitors; 2) PD-1/PD-L1 inhibitors + CT; 3) PD-1/PD-L1 + CTLA-4 inhibitors; 4) PD-1/PD-L1 + CTLA-4 inhibitors + CT; 5) CT. Outcomes were progression-free survival (PFS) and overall survival (OS). Bayesian random-effects models generated hazard ratios (HRs) with 95% credible intervals (CIs). Treatment rankings were assessed using surface under the cumulative ranking curve (SUCRA).

Results: The analysis included 8 trials (10 publications) encompassing 7,220 patients, of which 4,455 (61.7%) were mutation-evaluable (10.89% KEAP1, 12.37% STK11, 16.25% KRAS). For KEAP1-mutant tumors, PD-1/PD-L1+CTLA-4 inhibitors+CT showed superior OS versus CT alone (HR 0.48, 95% CI 0.25-0.91) and ranked highest, while PD-1/PD-L1 inhibitors+CT was most effective in wild-type. In STK11-mutant NSCLC, PD-1/PD-L1 inhibitors monotherapy significantly improved OS versus CT (HR 0.56, 95% CI 0.35-0.87; SUCRA top-ranked), contrasting with wild-type where PD-1/PD-L1 inhibitors+CT was superior. For KRAS-mutant disease, PD-1/PD-L1 inhibitors monotherapy (HR 0.42, 95% CI 0.21-0.85) and PD-1/PD-L1+CTLA-4 inhibitors+CT (HR 0.63, 95% CI 0.44-0.89) both outperformed CT alone, with monotherapy ranking highest; in KRAS G12C, PD-1/PD-L1 inhibitors monotherapy showed particularly striking benefit (HR 0.28, 95% CI 0.09-0.9). In wild-type tumors, PD-1/PD-L1 inhibitors+CT consistently ranked highest. PFS SUCRA results corroborated these findings.

Conclusions: This analysis suggests mutation-specific therapeutic responses. Better results were observed with PD-1/PD-L1+CTLA-4 inhibitors+CT for KEAP1-mutant, PD-1/PD-L1 inhibitors monotherapy for STK11- and KRAS-mutant (especially G12C), and PD-1/PD-L1 inhibitors+CT for wild-type NSCLC. These results highlight the importance of biomarker-driven selection of checkpoint inhibitors in the first-line setting in patients with KRAS, STK11, and KEAP1 alterations.

P1.11.70 Immune Cell Infiltration and Spatial Associations in the Tumor Microenvironment Following Dual ICI or ICI-Chemotherapy

M. Aminu, B. Zhu, M. Saad, H. Li, L. Hong, M. Qayati, A. Mehmet, S. Gandhi, L.M. Solis Soto, F.R. Rojas, S. Ou, T.I. Santiago, B.A. Burns, P.C. Edwin Roger, H. Chen, Y. Jie, S.G. Stephen, A.B. Mara, J.V. Pozadzides, G.J. Blumenschein, D.L. Gibbons, T. Cascone, Y.Y. Elamin, X. Li, M.V. Negrao, F. Skoulidis, T. Anne, J. Tu, J.L. Lee, J. Wu, J. Zhang, J.V. Heymach, N. Vokes
The University of Texas MD Anderson Cancer Center, Houston/TX/USA

Introduction: Immune checkpoint inhibition (ICI) with anti-PD-L1 inhibitors alone or in combination with anti-CTLA4 inhibition (dual-ICI) or with chemotherapy (ICI-chemo) induces complex changes in the tumor microenvironment (TME). The effects of these distinct treatment combinations on tumor-immune composition are poorly understood. Imaging mass cytometry (IMC) enables analysis of cell compositions and spatial associations in pre- and post-ICI lung tumor samples to elucidate differential immune responses and cellular interactions across treatment strategies.

Methods: Tumor samples from lung cancer patients receiving dual-ICI or ICI-chemo were collected. IMC was used to profile cell types and their spatial interactions within the TME. Statistical analyses were performed to identify significant differences in cell infiltration and spatial associations between treatment groups and response categories.

Results: Post-treatment samples from both treatment groups exhibited significantly higher infiltration of neutrophils, NK cells, and dendritic cells compared to pre samples ($p < 0.05$), indicating immune activation. However, Tregs were significantly elevated in the dual-ICI group ($p < 0.0005$) but not in the ICI-chemo group. Cellular heterogeneity analysis further showed that ICI-chemo samples had higher immune cell infiltration in both pre- and post-treatment samples, while epithelial cells were more abundant in dual-ICI post-treatment samples ($p < 0.0005$). Progressive disease (PD) in the dual-ICI group was associated with elevated epithelial cells and Tregs compared to responders, while PD in the ICI-chemo group was significantly associated with reduced monocytes, macrophages, and CD8 T cells ($p < 0.05$). Multicellular spatial analysis identified eight distinct spatial neighborhood structures. In post-treatment dual-ICI samples, one neighborhood exhibited high infiltration of B cells, dendritic cells, CD4 T cells, and CD11b+ myeloid cells, forming a robust and complex immune neighborhood. However, a shift in this neighborhood was observed in post-ICI-chemo samples, where only B cells and dendritic cells remained prominent, with CD4 T cells and CD11b+ myeloid cells no longer present. Additionally, cell-cell interaction patterns differed, with dual-ICI post-surgical samples showing active interactions among immune and stromal cells, while ICI-chemo post samples displayed avoidance patterns among B cells, dendritic cells, and NK cells with other cell types. Notably, epithelial cells in dual-ICI post samples exhibited an avoidance pattern with immune and stromal cells, while in ICI-chemo post samples, epithelial cells demonstrated active interactions with these cell types.

Conclusions: Dual-ICI or ICI-chemo induces distinct immune responses and spatial cellular arrangements in the TME. Dual-ICI is associated with epithelial cell persistence, higher Treg infiltration, and active immune-stromal cell interactions, though epithelial cells exhibit avoidance of these interactions, potentially contributing to progressive disease. In contrast, ICI-chemo promotes higher immune cell infiltration and altered spatial organization, with epithelial cells actively interacting with immune and stromal cells. These findings highlight the importance of spatial dynamics and cell-cell interactions in shaping treatment outcomes, offering insights for optimizing treatment strategies in cancer.

SUNDAY, SEPTEMBER 7, 2025 - 10:30 - 12:00

P1.11.71 RMT in Non Small Cell Lung Cancer

A. Kulkarni[1,2], R. Shanley[2], C. Staley[2], R. Maroney[2], K. Arends[2], S. Kagalwalla[2], B. Manning[2], N. Fujioka[2], R. Kratzke[2], A. Khoruts[2], M. Patel[2]
[1]City of Hope, Goodyear/AZ/USA ,[2]University of Minnesota, Minneapolis/MN/USA

Introduction: Multiple studies have shown that gut microbiome composition may modulate response to immune checkpoint inhibitors (ICI). Recent clinical trials in melanoma demonstrated safety and feasibility of fecal microbiota transplant (FMT) in combination with ICI. No study has demonstrated the safety and efficacy of FMT derived from healthy donors in patients receiving combination ICI and platinum-based chemotherapy. We report the preliminary safety and efficacy of restorative microbiota therapy (RMT) from the open-label safety-run-in portion of the randomized double-blind phase II Trial of RMT or placebo in combination with durvalumab and tremelimumab with chemotherapy in advanced Non-Small Cell Lung Cancer (NSCLC).

Methods: Patients with treatment-naïve locally advanced or metastatic NSCLC without actionable genomic alterations were enrolled. Eligible study participants received RMT, a standardized oral encapsulated formulation of freeze-dried microbiota derived from healthy donors manufactured by the University of Minnesota Microbiota Therapeutics Program. RMT was given weekly for 16 weeks and patients received the combination of durvalumab, tremelimumab and platinum doublet chemotherapy per the POSEIDON clinical trial. The co-primary endpoints were the safety and tolerability (NCI CTCAE v 5) and the efficacy using progression-free survival (PFS) per Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. Blood and stool were collected at frequent intervals. 16S ribosomal RNA (rRNA) sequencing was performed on the stool specimens and measures of diversity, and relative abundance were estimated. The present study reports the open-label safety component of the study participants who received RMT from a single donor.

Results: Ten participants were included in the analysis of safety and efficacy. Median age was 62 years (range 53-75 years), 55% were female and all patients had adenocarcinoma histology. Median follow-up time was 15 months (range 2-24 months). The most common AE probably or possibly related to RMT were diarrhea, bloating, constipation, anorexia, and fever. Grade ≥3 AE probably or possibly related to RMT and chemoimmunotherapy was 17%. There were no cases of bacteremia or treatment-related deaths. Four patients remain on the study treatment. Confirmed objective response rate was 50% (95% CI: 24, 76) and the median PFS was 5.3 months (95% CI 1.6, NE). Exploratory analysis of 16S rRNA sequencing data (N=9) showed that the relative abundance of Collinsella was higher in responders compared to non-responders.

Conclusions: We report that the combination of microbiota therapy with chemoimmunotherapy appears to be safe with no new toxicity signal. Preliminary efficacy is promising, and the randomized double-blind placebo-controlled study is ongoing. Early data suggest that Collinsella in the stool is associated with treatment response.

P1.11.72 Phase II Study of Combination Azacitidine and Entinostat and Nivolumab in Patients With Metastatic Non-Small Cell Lung Cancer

K.A. Marrone[1], B. Landon[1], H-L. Tsai[1], M. Topper[1], C. Hu[1], J.J. Nieva[2], J. Herman[3], P.M. Forde[1], C.L. Hann[1], D. Ettinger[1], R. Kelly[4], S.B. Baylin[1], V. Anagnostou[1], J.R. Brahmer[1]
[1]Johns Hopkins University School of Medicine, Baltimore/MD/USA ,[2]Keck School of Medicine of University of Southern California, Los Angeles/CA/USA ,[3]University of Pittsburgh Medical Center, Pittsburgh/PA/USA ,[4]Baylor Scott & White Health, Dallas/TX/USA

Introduction: Emergence of resistance to immune checkpoint blockade (ICB) mandates the development of strategies for ICB sensitization. Epigenetic targeting agents with ICB represent a novel combinatorial approach to enrich anti-tumor immunity in non-small cell lung cancer (NSCLC). Hypermethylation of DNA promoter regions by DNA methyltransferases (DNMT) and histone deacetylation by histone deacetylases (HDAC) are two key epigenetic regulatory mechanisms, with preclinical studies showing that HDAC and/or DNMT inhibition can induce susceptibility to ICB and inhibit tumor growth. Herein, we will present results of completed arms from a clinical trial of combination epigenetic therapy with concurrent nivolumab.

Methods: Patients with previously treated metastatic NSCLC were enrolled into this multi-institutional platform phase II study (NCT01928576). Treatment arm assignment was defined by prior ICB treatment status and related disease response. Arm D enrolled ICB-naïve patients; Arm E enrolled patients with ICB-refractory disease (progression within 6 months of ICB initiation); and Arm F enrolled ICB-pretreated patients (stable disease ≥ 6 months on prior ICB therapy). Study treatment for all patients was combination azacitidine (40 mg/m2 subcutaneous days 1-5, 8-10), entinostat (4 mg by mouth days 3 and 10) and nivolumab (3 mg/kg IV days 1 and 15) for 6 cycles, followed by nivolumab alone. The primary endpoint of the study is overall response rate (ORR) by Arm. Secondary endpoints include time to progression (TTP), 24-week progression-free survival (24 wk-PFS), median overall survival (mOS) and safety and tolerability.

Results: Between September 2017 and January 2022, 40 patients enrolled in the trial to Arm D (n=14), Arm E (n=7) and Arm F (n=19) respectively. ORR was 21% (95% CI: [5-51%]) on Arm D, 14% [0-58%] on Arm E and 11% on Arm F [1-33%]. Median TTP was 7.8 months on Arm D, 4.9 months on Arm E and 3.8 months on Arm F. 24wk-PFS in Arm D was 57% [36-90%], in Arm E was 29% [9-92%], and in Arm F 42% [25-71%]. mOS for Arm D was 24.6 months, for Arm E 5.0 months and 12.1 months for Arm F. One patient on Arm E experienced two dose-limiting toxicities attributed to study treatment (dyspnea, vomiting); one treatment-related serious adverse event (trSAE) was seen on Arm D, and 5 trSAEs were reported in two patients on Arm E.

Conclusions: Concurrent combination epigenetic therapy with ICB was safe for patients with previously treated advanced NSCLC regardless of prior ICB exposure. This combination was encouragingly efficacious in the post-ICB setting. Patients treated on Arm F were found to have promising clinical benefit following previous disease progression on standard treatment approaches. Further correlative evaluation, including in-depth genomic and transcriptomic analyses, are ongoing to accurately identify patients most likely to benefit from this therapeutic approach. Final integration of these translational studies with clinical outcomes will work to identify the biologic effect of epigenetic therapy in re-shaping the tumor microenvironment to personalize this epigenetic combinatorial approach.

P1.11.73 Tiragolumab Plus Atezolizumab and Bevacizumab in Immunotherapy-Refractory, Pd-L1+, Advanced Non-Squamous Non-Small Cell Lung Cancer

J. Reuss[1], J. Ahn[1], C. Kim[1], K.N. Smith[2], S. Byers[1], K. Creswell[1], C.M. Merkhofer[1], J.E. Thompson[1], J.T. Nawrocki[1], J. Crawford[1], E. Cohen[1], J. Zeck[1], M. Gutierrez[3], S.V. Liu[1]
[1]Georgetown Lombardi Comprehensive Cancer Center, Washington/DC/USA ,[2]Johns Hopkins Sidney Kimmel Comprehensive Cancer Center, Baltimore/MD/USA ,[3]John Theurer Cancer Center, Hackensack/NJ/USA

Introduction: Treatments for checkpoint inhibitor immunotherapy (CPI)-refractory advanced non-small cell lung cancer (NSCLC) are limited. Inhibition of vascular endothelial growth factor (VEGF) has demonstrated synergy in combination with PD-(L)1 blockade in both CPI-naïve and -refractory NSCLC. Blockade of T-cell immunoglobulin and ITIM domain (TIGIT) has also shown synergy when combined with anti-PD-(L)1 CPI, and translational work indicates tumor infiltration with immune inhibitory cells (regulatory T-cells, macrophages) are critical to anti-tumor efficacy of anti-TIGIT CPI. This suggests TIGIT-based therapies may be best-positioned for CPI-resistant/refractory disease in which these cell populations are commonly enriched. Here we present interim data from a multi-cohort single-arm phase 2 trial of tiragolumab (anti-TIGIT) plus atezolizumab (anti-PD-L1) and bevacizumab (anti-VEGF) in immunotherapy-refractory, PD-L1+, advanced non-squamous NSCLC (NCT04958811).

Methods: In cohort A of this study, patients with advanced PD-L1+ (tumor proportion score (TPS) ≥ 1%), EGFR/ALK/ROS1 wild-type, non-squamous NSCLC with progression on prior anti-PD-(L)1-based CPI are treated with tiragolumab 600 mg IV with atezolizumab 1200 mg IV and bevacizumab 15 mg/kg IV every 3 weeks until progressive disease or unacceptable toxicity. The primary endpoint is investigator-assessed objective response rate (ORR) according to RECIST v1.1, utilizing a Simon 2-stage design in which a null ORR of 4% is tested against a one-sided alternative of 20%. A sample size of 21 patients provides 80% power with a one-sided type 1 error rate of 5% to determine a true ORR of 20%. Key secondary endpoints are investigator-assessed progression-free survival (PFS), overall survival (OS) and safety (assessed by frequency of treatment-emergent adverse events [TEAEs]). Pre- and on-treatment blood and tumor specimens are being collected for translational analyses.

Results: In stage 1 of the Simon 2-stage design, 12 patients were enrolled. Median age was 63.5 years, 58% of patients were female, and 75% had a history of current or prior smoking. Median number of prior lines of therapy was 1 (range: 1-3) and 58% had PD-L1 high (TPS ≥ 50%) disease. The investigator-assessed ORR was 25% (95% confidence interval (CI), 9.0 - 53.0) with a disease-control rate of 83% (95% CI, 55.0 - 95.0). At a median follow-up of 10.7 months, the median PFS was 4.8 months (95% CI, 2.6 - Not Reached [NR]) and the median OS was 21.5 months (95% CI, 7.7 - NR). Nine patients (75%) experienced a grade ≥3 TEAE, of which hypertension (2 patients - 15%) and pneumothorax (2 patients - 15%) were most common. In both instances, pneumothorax occurred spontaneously in setting of documented bullous emphysema and was adjudicated unrelated to therapy. Four patients (33%) experienced a grade ≥3 treatment-related adverse event, among which hypertension (15%) was most common.

Conclusions: Tiragolumab plus atezolizumab and bevacizumab demonstrates a promising efficacy signal with favorable toxicity profile in patients with advanced PD-L1+, CPI-refractory, non-squamous NSCLC. Based on these data, and per protocol, the study will proceed to the second stage of the Simon 2-stage design. Planned tissue and blood correlates will explore immunologic, molecular, and pathologic response features to identify patient subsets most likely to benefit from this approach.

P1.11.74 Phase Ib Study of Golidocitinib Plus Anti-PD-1 in Anti-PD-1 Treated Advanced NSCLC: Dose-Escalation Safety Using BOIN Design

H. Zhong, X. Zhang, B. Han
Shanghai Chest Hospital, Shanghai Jiao Tong University, Shanghai/CN

Introduction: Resistance to first-line immune checkpoint inhibitors (ICIs) in non-small cell lung cancer (NSCLC) leads to limited treatment options and poor prognosis. Preclinical and early clinical data have shown synergistic effects between JAK inhibitors and anti-PD-1, suggesting a promising therapeutic strategy in this population. Our study evaluates Golidocitinib, a selective JAK1 inhibitor, in combination with Anti-PD-1 in patients with locally advanced or metastatic NSCLC who progressed after first-line Anti-PD-1 therapy. The study aims to determine the safety, tolerability, and preliminary efficacy of this combination, addressing a critical unmet need in overcoming immune resistance. The dose-exploration phase employs a Bayesian Optimal Interval (BOIN) design to determine the recommended expansion phase combination dose.

Methods: This study is a phase Ib, single-center, single-arm exploratory clinical study. The BOIN design to establish a safe dose of Golidocitinib with anti-PD-1. Patients received oral Golidocitinib at either 75 mg or 150 mg once daily, combined with an anti-PD-1 (200 mg, intravenous, every 3 weeks). Dose-limiting toxicities (DLTs) were evaluated over a 28-day period (first cycle plus 7 days) to establish the combination dose, with 3-6 patients(pts) per dose level. Following dose escalation, the study transits to an expansion phase at the selected dose to assess antitumor efficacy, with the primary endpoint of objective response rate (ORR) per RECIST 1.1 criteria. Secondary endpoints included progression-free survival (PFS), duration of response (DOR), overall survival (OS), and safety.

Results: In the BOIN dose-escalation phase, 6 patients were enrolled: 3 received Golidocitinib at 75 mg daily and 3 at 150 mg daily, each combined with anti-PD-1. No DLTs were observed in either cohort during the 28-day DLT assessment period, indicating good tolerability and safety. Grade 2 adverse events (AEs) were observed as neutropenia (2 pts), hypertriglyceridemia (2 pts), leukopenia (1 pt), thrombocytopenia (1 pt) and proteinuria (1 pt) in 4 patients. Additionally, one patient reported a cardiac-related Grade 2 AE (manifested as atrial fibrillation, rapid ventricular rate and aberrant conduction). No adverse events greater than Grade 2 were reported. Based on the BOIN algorithm and absence of DLTs, the 150 mg dose was selected as the combination dose. The study will now expand to enroll a total of 30 patients to further evaluate safety and efficacy, focusing on ORR as the primary measure of antitumor activity.

Conclusions: The combination of Golidocitinib at 150 mg daily with anti-PD-1 was well-tolerated in immune-resistant NSCLC patients, with no DLTs observed in the dose-escalation phase. These preliminary results support progression to the expansion phase, where safety and therapeutic potential will be further explored. This approach holds promise as a novel strategy to overcome resistance to prior ICIs therapy in NSCLC population. Ongoing enrollment and data collection will provide deeper insights into its clinical utility.

P1.11.75 A Phase 2 Study of PCSK9 Inhibitor, Alirocumab, and PD1 Inhibitor, Cemiplimab, in Advanced Immunorefractory Metastatic NSCLC

E. Oduah[1,2], N. Ready[1,2], J. Clarke[1,2], J. Rivera Concepcion[1,2], J. Crawford[1,2], L. Alder[1,2], J. Gray[3], T. Stinchcombe[1,2], S. Antonia[1,2]
[1]Duke University, Durham/NC/USA ,[2]Duke Cancer Institute, Durham/NC/USA ,[3]Moffitt Cancer Center, Tampa/FL/USA

Introduction: For most NSCLC patients, overcoming immunotherapy resistance remains a critical challenge. In preclinical models, PSCK9 mediated immune checkpoint inhibitor (ICI) resistance by degrading MHC1 molecules. Further, PCSK9 inhibition synergized with anti-PD1 antibody to induce cytotoxic CD8+ T cell activation and intratumoral penetration to enhance anti-tumor activity.

Methods: TOP 2201 is a phase II, single arm trial designed to evaluate the clinical activity and safety of alirocumab (PCSK9 inhibitor) in combination with cemiplimab (anti-PD1 antibody) in patients whose tumors were ICI resistant. The primary endpoint is objective response rates (ORR). Secondary endpoints include progression free survival (PFS), overall survival (OS), duration of responses (DOR), disease control rates (DCR) and safety. Correlative objectives include biomarker analysis to identify predictors of response.

Results: Forty patients were enrolled between May 2023 and November 2024 (data cut off). The ORR in the intention-to-treat (ITT) population was 14.7%. When stratified by histology, the ORR was 36.4% in squamous and 3.6 % in non-squamous histology. The DCR in the study population was 83.2%. Amongst responders, the median DOR was 9.9 months (95% CI, 4.2 - 15.8). The median PFS was 3 months (95% CI, 2.6 - 5.5) for the ITT population. By histology, the median PFS was 5.5 months (95% CI, 0.8 - 17), and 2.8 months (95% CI, 2.1 - 4.1) for the squamous and non-squamous respectively. In the ITT population, the median OS was 7 months (95% CI, 3 - 13); the 6-month and 12-month OS rates were 61% and 49.5% respectively. By histology, the 6-month OS rate was 82% for squamous and 54% for non-squamous, while the 12-month OS rate was 71.6% and 40.4% for squamous and non-squamous respectively. Exploratory analysis revealed that the presence of oncogenic alterations in PIK3CA/AKT1/PTEN was significantly associated with improved outcomes. The ORR of patients with alterations in PIK3CA/PTEN/AKT1 was 50% (95% CI, 24 - 73) whereas in patients without these alterations the ORR was 0%. The median DOR in the presence of the alterations was approximately 10 months (95% CI, 4.2 - 15.8). When stratified by the presence alterations, the median PFS was 14.9 months (95% CI, 0.8 - 17) vs 2.7 months (95% CI, 0.8 - 17) in the altered vs unaltered groups respectively. The presence of PIK3CA/PTEN/AKT1 alteration predicted a statistically significant improvement in PFS with a HR of 0.26 (95% CI, 0.13 - 0.5; p 0.0012). There was trend towards improved OS in the altered versus unaltered group, but it did not reach statistical significance, HR 0.4 (95% CI, 0.16 - 0.99; p 0.07). There were no unexpected safety signals.

Conclusions: Alirocumab added to cemiplimab was well tolerated and reversed immunotherapy resistance in a subset of patients. Notably, patients with squamous histology demonstrated improved ORR and survival benefit compared to non-squamous histology. The response pattern seen with alterations in PIK3CA/PTEN/AKT1 suggest that PIK3CA/PTEN/AKT1 could be biomarkers of response to PCSK9-based combinations. Confirmation of these findings are needed in larger studies. The impact of PIK3CA/PTEN/AKT1 alterations on PCSK9 biology is being investigated in preclinical models.

Introduction: Although the quadruple regimen combining bevacizumab, immunotherapy, and platinum-based doublet chemotherapy has become a primary treatment option for EGFRmut non-squamous non-small cell lung cancer (nsq-NSCLC), its clinical benefits in EGFR-TKI-resistant populations remain controversial. Therefore, we initiated a phase 2 study to investigate the feasibility, efficacy, and safety of bevacizumab (HLX04) combined with serplulimab (HLX10) and standard chemotherapy in EGFR-TKI-resistant nsq-NSCLC patients.

Methods: This is a multicenter, single-arm phase 2 trial (NCT06334757). The main inclusion criteria are adults aged 18-70 years with EGFRmut nsq-NSCLC, Eastern Cooperative Oncology Group performance status (ECOG PS) 0-1, documented disease progression after first- to third-generation EGFR-TKI therapy (≤2 lines), and no history of immunochemotherapy exposure. Eligible patients receive 4-6 cycles of HLX04 (7.5 mg/kg, day 1) plus HLX10 (300 mg, day 1), in combination with standard chemotherapy consisting of pemetrexed and carboplatin every 3 weeks, followed by maintenance therapy with HLX04 plus HLX10 and pemetrexed until progression, unacceptable toxicity, or up to 2 years (35 cycles). After considering both safety profiles and socioeconomic burden, the bevacizumab dose of 7.5 mg/kg was selected for this study. The primary endpoint is the objective response rate (ORR). The secondary endpoints include progression-free survival (PFS), overall survival (OS), disease control rate (DCR), time to response (TTR), duration of response (DoR), and safety.

Results: This study enrolled 46 patients from nine centers across China. The median age was 59 (range: 36 - 70); 63.0% were female, 73.9% were non-smokers, 95.7% had an ECOG PS of 1, and 54.4% had brain metastases. Thirty-four patients (73.9%) failed on prior first-line EGFR-TKI treatment. Thirty-three patients (71.7%) previously received a third-generation EGFR-TKI only. One patient had a confirmed complete response, and 21 had partial responses, resulting in an ORR of 47.8% (95% CI: 32.9 - 63.0%) and achieving the predefined target of 45.0%. The DCR was 87.0% (95% CI: 73.7 - 95.1%). As of March 4, 2025, the median follow-up was 8.8 months. A total of 25 PFS events were reported, with a median PFS of 7.7 months (95% CI: 7.0 - NR) and a 6-month PFS rate of 68.3% (95% CI: 55.8 - 83.6%). The median TTR and DoR were 1.5 months (95% CI: 1.4 - 2.8) and 6.2 months (95% CI: 5.3 - NR), respectively. OS data remained immature, with three deaths reported. Subgroup analyses revealed that patients without brain metastases were more likely to achieve better efficacy, with an ORR of 52.4% vs. 44.0% and a median PFS of 9.5 vs. 7.1 months. No statistically significant differences in PFS were observed among patients stratified by prior therapy lines or EGFR-TKI agents. The incidence of any grade of adverse events (AEs) was 80.4% (37/46). Seventeen (37.0%) patients experienced grade ≥3 AEs; neutrophil count decreased (12/46, 26.1%) was the most frequent, followed by white cell count decreased (9/46, 19.6%) and platelet count decreased (8/46, 17.4%).

Conclusions: These findings indicated that a dose-reduced bevacizumab regimen combined with serplulimab and platinum-based doublet chemotherapy exhibited promising efficacy and manageable safety for patients with EGFR-TKI-resistant nsq-NSCLC.

P1.11.77 A Comprehensive Analysis of Front-Line Regimens for Stage IV Non-Squamous Non-Small Cell Lung Cancer: A 13-Year Experience

N. Rehman[1], A. Dhakal[1], B. Adcock[1], M. Alchiarazi[1], M. Albliwi[1], A. Mushtaq[1], H. Zureigat[1], M. Lee[1], A. Hassan[1], S. Haddad[1], H. Batah[1], P. Patel[1], E. Zabor[1,2], L. Delasos[1,2], K. Hassan[1,2], N. Pennell[1,2], M. Shapiro[1,2], J. Stevenson[1,2], A. Adjei[1,2], M.K.M. Ali[1,2]
[1]Cleveland Clinic Foundation, Cleveland/OH/USA ,[2]Taussig Cancer Institute, Cleveland/OH/USA

Introduction: Advances in immunotherapy and targeted therapy have reshaped the standard of treatment for stage IV non-squamous (NS) non-small cell lung cancer (NSCLC). However, there is a paucity of real-world data comparing the previous standard of treatment to modern regimens. In this retrospective study we analyzed the overall survival (OS) in stage IV NS NSCLC treated with standard chemotherapy (CTX) compared to modern regimens.

Methods: We conducted a retrospective analysis of de novo stage IV NS NSCLC at time of diagnosis treated at Cleveland Clinic, OH from 1/2010-12/2022. Baseline variables including age at diagnosis, sex, race, performance status, smoking history, PDL1 testing and molecular profiling were collected along with treatment regimens. Treatment response was assessed using RECIST 1.1 response criteria. OS was calculated from date of first therapy. Multivariable cox hazard regression (CPH) was used to adjust for confounding. We compared two groups: 1) immunotherapy (IT), CTX-immunotherapy (CTX + IT) and targeted therapies which were grouped as “modern therapies” and 2) conventional CTX.

Results: We identified 1,518 patients with NS NSCLC, of which 97% had adenocarcinoma (N = 1471). Median age at diagnosis was 65 (IQR 58-73). 51% of the patients were female, 82% were white and 42% were current smokers. Treatments administered included conventional CTX (744, 49%), IT (186, 12%), CTX+IT (318, 21%), and targeted therapy (270, 18%). The most common regimens were carboplatin + pemetrexed/paclitaxel (N = 502, 80%) and bevacizumab + carboplatin + pemetrexed/paclitaxel (N = 127, 20%) for CTX, pembrolizumab (N = 167, 89%) for IT and carboplatin + pemetrexed + pembrolizumab (N = 153, 41%) for chemo-IT. Overall response rate was 58% with median follow-up of 47.5 months. The 2 and 5-year OS were 30% (95%CI 28-33) and 12% (95%CI 10-14). On multivariable CPH, modern regimens improved OS by 28% compared to conventional CTX (HR 0.72, 95%CI 0.65-0.81, p < 0.001). In the conventional CTX group, bevacizumab + carboplatin + pemetrexed/paclitaxel was associated with improved OS compared to carboplatin + pemetrexed/paclitaxel (HR 0.75, 95%CI 0.59-0.94, p = 0.012) and pemetrexed was superior to paclitaxel (HR 0.79, 95%CI 0.63-0.99, p = 0.047). Using multivariable CPH, front-line Osimertinib (N = 81) was associated with improved OS compared to erlotinib (N =93) in EGFR mutated NS NSCLC (HR 0.59, 95%CI 0.42-0.84 p = 0.003) but not afatinib (n=26) (HR 0.80, 95%CI 0.48-1.33, p = 0.013). In ALK mutated NS NSCLC, multivariable CPH showed that front-line crizotinib (N =20) was associated with worse OS than alectinib (N = 28) (HR 4.4, 95%CI 1.87-10.6, p < 0.001)

Conclusions: In the largest retrospective study of stage IV NS NSCLC, we confirmed that modern regimens improved OS by 28% compared to conventional CTX. Despite that, long term survival remains poor and further research is needed.

P1.11.78 NAI, An IL-15 Superagonist, A New Class Of Lymphocyte Stimulating Agent (LSA) Prolongs OS In NSCLC By Reversing Lymphopenia

P.B. Soon-Shiong[1], J. Wrangle[2], D. Morgensztern[3], L. Raez[4], L. Sender[5], P. Yang[6], P. Bhar[6], L. Roycroft[6], H. Zhang[6], P.R. Spilman[6], S. Reddy[6]
[1]ImmunityBio, El segundo/CA/USA ,[2]Medical University of South Carolina, Charleston/SC/USA ,[3]Washington University, St. Louis/MO/USA ,[4]Memorial Healthcare System, Pembroke Pines/FL/USA ,[5]ImmunityBio, Inc., El segundo/CA/USA ,[6]ImmunityBio, Inc., Culver City/CA/USA

Introduction: Prior to the approval of Nogapendekin alfa inbakicept (NAI), an IL-15 superagonist which stimulates lymphocytes important in immunogenic cell death (Natural killer cells, CD4+ CD8+ T cells and memory T cells), no treatment existed to address lymphopenia as measured by the absolute lymphocyte count (ALC) in the CBC differential. Severe lymphopenia (ALC<1,000), associated with the adverse effects of chemotherapy, radiation, steroids and CPI, significantly lowers overall survival in NSCLC. While absolute neutrophil count (ANC) is widely used to identify neutropenic fever risk, ALC has been largely ignored by clinicians since no therapy existed to treat lymphopenia. To test the hypothesis that NAI, a novel immunotherapy and first-in-class lymphocyte stimulating agent (LSA), prolongs OS by reversing lymphopenia and maintains median ALC≥1,200, a Phase 2 study was conducted wherein patients with NSCLC with acquired resistance to CPI therapy were treated with the same CPI+NAI, a chemo-free combination (QUILT-3.055 NCT03228667). The effect of reversing lymphopenia and maintaining ALC≥1,500 was studied to examine the hypothesis that proliferating NK and T cells with improved ALC results in prolonged OS.

Methods: The change in ALC (absolute cell count and percentage change from baseline) with NAI and CPI during study and its relationship to median OS was the primary endpoint for LSA. Statistical differences between the OS in patients who failed to achieve ALC≥1,000 versus those who overcame severe lymphopenia (ALC<1,000) and those who maintained ALC≥1,500 were measured.

Results: The median OS for 2nd line (51%) and 3rd line+ (49%) was 14.3 months (95% CI 11.7, 17.4) with 23 of 86 subjects alive at data cutoff (Dec 2024). With NAI, 69/86 (80%) exceeded the median ALC 1,200 with a median OS of 15.8 months (12.6, 21.9). Of these 69 subjects, 44/69 (64%) maintained an average ALC≥1,500 throughout study therapy with median OS 21.1 months (13.9, 42.1) and significantly prolonged (HR: 0.33 [0.16, 0.65], p=0.0009) compared to subjects who failed to achieve ALC 1,200 with median OS 11.5 months (4.2, 13.3).

Conclusions: For the first time, ALC is an actionable accessible biomarker to recognize and treat lymphopenia induced by chemotherapy, radiation, steroids and immunotherapy and to prolong OS with NAI. Lymphopenia is addressed for the first time with availability of this new class of lymphocyte stimulating agent (LSA), NAI. When ALC is maintained ≥1,500 with NAI, the immune system is effectively activated (chemo-free), and median OS is significantly prolonged at 21.1 months, HR: 0.33 (95% CI:0.16,0.65) P=0.0009.

P1.11.79 A Meta-Analysis on Anti-PD-1/L1 With or Without Anti-VEGF Plus Chemotherapy in EGFR-Mutant or ALK-Rearranged NSCLC Progressing on TKIs

R.J.N. Velasco[1], M.S.B. Imasa[1], G.E.I.R. Ladrera[1], H.N.C. Tan[2], A.C. Tan[3], A.E.D. Drilon[4]
[1]Lung Center of the Philippines, Quezon City/PH ,[2]MD Anderson Cancer Center, Houston/TX/USA ,[3]National Cancer Center Singapore, Singapore/SG ,[4]Memorial Sloan Kettering Cancer Center, New York City/NY/USA

Introduction: Non-small cell lung cancer (NSCLC) is commonly diagnosed at an advanced stage with a high predilection for distant metastasis. Despite available treatment options for epidermal growth factor (EGFR)-positive and anaplastic lymphoid kinase (ALK) fusion-positive disease in the advanced and metastatic stage, the prognosis remains dismal on progression with limited treatment options after the use of tyrosine kinase inhibitors (TKI). Although studies have shown that immune checkpoint inhibitors (ICI) have limited benefit for oncogene-driven lung cancer, with more associated adverse events when given after TKIs, several trials have been conducted with conflicting results. This systematic review and meta-analysis examined the efficacy and safety of anti-PD-1/L1 among patients with metastatic non-small cell lung cancer progressing after targeted therapy.

Methods: A systematic search was done using PUBMED, Cochrane, and Clinicaltrials.gov for articles published until March 23, 2025 to examine the effect and safety of anti-PD-1/L1 with or without anti-vascular endothelial growth factor (VEGF) plus chemotherapy after progression on prior TKIs compared with chemotherapy and placebo in locally advanced or metastatic NSCLC. Phase III randomized controlled trials (RCT) which included patients with advanced NSCLC who progressed on TKI treatment for EGFR mutation or ALK translocation with no previous chemotherapy were included. The outcomes investigated were progression-free survival (PFS), overall survival (OS), and > grade 3 treatment-related adverse events (AEs). Data on PFS, OS, and AEs were extracted from the included studies. Hazard ratios (HR) for survival and relative risk (RR) for the adverse events with 95% confidence intervals (CI) were pooled from the included studies and summarized using RevMan 5.3.

Results: This pairwise meta-analysis included five phase III RCTs (CheckMate 722, ATTLAS-KCSG-LU19-04, HARMONi-A, KEYNOTE-789, and ORIENT-31) with 1, 812 patients. Anti-PD-1/L1 with chemotherapy improved PFS compared with chemotherapy and placebo (HR 0.76; 95% CI 0.66, 0.88) and OS (HR 0.86; 95% CI 0.75, 1.00). Anti-PD-1/L1 with anti-VEGF and chemotherapy improved PFS compared with chemotherapy and placebo (HR 0.52; 95% CI 0.44, 0.62) with no effect on OS (HR 0.99; 95% CI 0.78, 1.26). OS data was not yet available for HARMONi-A due to the short-term follow-up, hence, excluded from OS analysis. There were more associated > grade 3 treatment-related AEs on the use of anti-PD-1/L1 with or without anti-VEGF plus chemotherapy compared with chemotherapy and placebo (RR 1.26; 1.03, 1.54). There was no observed heterogeneity for all outcomes except for the occurrence of adverse events (I2 67%).

Conclusions: Anti-PD-1/L1 with chemotherapy improved PFS and OS, while anti-PD-1/L1 with anti-VEGF and chemotherapy improved PFS with no effect on OS. The use of anti-PD-1/L1 with anti-VEGF and chemotherapy was associated with a higher risk of > grade 3 treatment-related AEs, thus, warrants careful monitoring. Anti-PD-1/L1 with or without anti-VEGF plus chemotherapy is a novel and promising approach for NSCLC patients with EGFR mutation or ALK translocation progressing on prior TKIs. Longer follow-up of the included trials is recommended.

P1.11.80 Tumor-Derived Complement Factor B Drives Tumor Growth and Anti-PD-1 Resistance in STK11-Mutant Lung Adenocarcinoma

S. Suzuki[1], B. Kandar[1], A.N.H. Khan[2], P. Deraska[1], T. Giridharan[1], H. Yu[1], B. Segal[2], E. Yau[1]
[1]Roswell Park Comprehensive Cancer Center, Buffalo/NY/USA ,[2]Moffitt Cancer Center, Tampa/FL/USA

Introduction: Loss-of-function STK11 mutations occur in 15-20% of lung adenocarcinomas (LUAD) and correlate with immunotherapy failure and poor outcomes. C3 production was increased in human STK11-mutant versus STK11-wild-type LUAD, and high C3 mRNA expression in STK11-mutant LUAD was associated with worse survival. Stk11 deletion (STK11-KO) in syngeneic murine CMT167 tumors (a spontaneous KrasG12V murine LUAD tumor model) resulted in increased neutrophil and reduced T cell infiltration and anti-PD-1 resistance similar to human STK11-mutant LUAD. C3 deletion in STK11-KO tumors resulted in dramatic inhibition of tumor growth and enhanced sensitivity to anti-PD-1 in immunocompetent mice but had little effect following CD8 depletion or in nude mice, pointing to tumor-derived C3 promoting immune evasion. Comparison of gene expression in STK11KO and STK11KO-C3KO tumor showed that C3 modulates expression of multiple complement genes including complement Factor B (CFB), which is required for alternative complement pathway activation through the alternative pathway (AP) C3 and C5 convertases. We hypothesized that tumor-derived CFB promotes growth and anti-PD-1 resistance in STK11-mutant tumors.

Methods: We used transient CRISPR-Cas9 RNP transfection to generate CMT167-STK11KO tumor cells with CFB deletion (CMT167-STK11KO-CFBKO) while avoiding the immunogenic effects of lentiviral based systems. We compared the subcutaneous tumor growth of CMT167-STK11KO-CFBKO and CMT167-STK11KO LUAD cells in immunocompetent mice to evaluate the effect of tumor-derived CFB in vivo. Iptacopan is an oral CFB inhibitor approved for paroxysmal nocturnal hemoglobinuria. We evaluated whether Iptacopan could overcome in-vivo anti-PD-1 resistance of CMT167-STK11KO tumors.

Results: Knockout of CFB resulted in robust inhibition of STK11KO tumor growth in immunocompetent mice. Combination treatment with CFB inhibitor Iptacopan and anti-PD-1 reduced STK11KO tumor growth and extended survival of mice.

Conclusions: Our results extend our prior findings of tumor-derived C3 promoting immune evasion in STK11-mutant LUAD and identify tumor-derived CFB in promoting tumor growth and immune check point inhibitor (ICI) resistance. These results identify tumor-derived C3 and CFB as a novel signaling axis to target in STK11-mutant LUAD and point to the potential role of the alternative complement pathway in tumor immune evasion. These results also provide rationale for an early phase clinical trial of CFB inhibitors such as Iptacopan to enhance anti-PD-1 effectiveness in patients with STK11-mutant LUAD.

P1.11.81 Low-Dose Nivolumab With Platinum Doublet Chemotherapy in Patients With Advanced Central Squamous Cell Lung Cancer (SCAR)

P.K. Singh[1], V. Surapaneni[2], G. Arya[3], A. Ahuja[3], S. Chougale[3]
[1]Pt BDS Post Graduate Institute of Medical Sciences, Rohtak/IN ,[2]Pt B D Sharma Post Graduate Institute of Medical Sciences, Rohtak, Rohtak/IN ,[3]Pt BDS Post Graduate Institute of Medical Sciences, Rohtak, Rohtak/IN

Introduction: Immune-checkpoint-inhibitors (ICI) have revolutionized the management of NSCLC. Despite the survival evidence, access to ICI remains limited especially in low- and middle-income countries due to prohibitive cost. Low dose ICIs have been studied in anecdotal cases and shown to have non-inferior results, though prospective and robust trials are missing. Nivolumab achieves 70-90% PD-1 occupancy at a dose level of 0.1-0.33mg/kg. With a half-life of 25 days we hypothesized that 20mg flat-dose of Nivolumab will continue to demonstrate meaningful clinical benefit in patients of NSCLC. Based on the prior results of low-dose nivolumab with chemotherapy in head-neck tumors and results of exploratory analysis of CheckMate-227 part-2, we selected cases of central-squamous-tumors for our study.

Methods: It was a single-arm, open-label, phase-2 clinical trial on treatment naïve NSCLC patients with squamous-histology. Inclusion criteria included, current-smokers, target lesion present in central-area (defined as within inner one third section from the major airways) with stage IIIB or higher and not amenable for definitive surgery/chemoradiotherapy. Primary-endpoint included objective-response-rates (ORR) and secondary endpoints included progression-free-survival, overall-survival and disease-control-rates.

Results: Over six months, 29 patients were screened, and 19 were enrolled. Of these, 18 were males, with a mean pack-year history of 28.3±10, and mean age 61.32±7.9 years (table 1). ECOG performance status of 2 and stage IIIB were seen in 52.6% (each). Eleven had chronic obstructive pulmonary disease. Main bronchi involvement was noted in 84.2%, and tracheal infiltration in 21%. After a median follow up of 128 days, 8 (42.1%) patients progressed and 6 (31.6%) died. 12 (63.1%) patients had a decrease in target lesion size of which 10 had >30% decrease suggestive of Partial Remission (as per RECIST 1.1). 4 patients had stable disease, and one had progressive disease, as best response. 4 patients died before first imaging for response assessment. ORR was 52.6% and DCR was 73.7%. 9 patients demonstrated an improvement in Karnofsky Performance Status of minimum 10 points. None of the patients reported any immune-related-adverse-events.

Conclusions: ORR in our study was lower than that of Nivolumab with chemotherapy arm of Checkmate227 part-2 squamous sub-group (60% versus 52.6%) but still better compared to only chemotherapy arm (52.6% versus 32%). The initial results of SCAR trial show encouraging results favouring the use of low dose nivolumab in central squamous cell NSCLC cases.

Introduction: Despite advancements in third line treatments, long-term survival for advanced non-small cell lung cancer (NSCLC) remains suboptimal, with median survival follow-up of only 5.8 months. (1) Treatment options for immune checkpoint inhibitor (ICI)-resistant patients are limited. THIO, a telomere-targeting agent that modifies telomeres in cancer cells, demonstrates improved progression-free survival (PFS) independent of PD-L1 expression.

Methods: NCT05208944 is a phase 2, multicenter, open-label study that enrolled 79 patients with advanced NSCLC who relapsed after 1-4 prior treatments, including ICIs. In the third line therapy 22 patients treated with THIO (60, 180, or 360 mg) were evaluated for (PFS) and their prior PD-L1 expression at the time of study enrollment (C1D1).

Results: In the third line therapy 17 out pf 22 patients (77%) surpassed the benchmark value, and in the 180 mg dose group (n=10) it reached 24.1 weeks. The response to THIO and cemiplimab, demonstrated by partial response (PR) and stable disease (SD) was independent of baseline PD-L1 status. This indicates that THIO can be effective across patients regardless of their PD-L1 status as cemiplimab alone provides survival benefit to advanced NSCLC patients with PD-L1 tumor expression of at least 50% (2).

Conclusions: THIO demonstrates clinically meaningful PFS improvement in third line patients with advanced NSCLC, independent of PD-L1 status. The improved (PFS) observed in patients treated with THIO in sequential combination with an immune checkpoint inhibitor (ICI), compared to standard chemotherapy, supports its potential to expand treatment options for ICI-resistant advanced NSCLC.

Introduction: Ivonescimab is a novel, investigational bispecific antibody against programmed cell death-1 (PD-1) and vascular endothelial growth factor (VEGF). The phase 3 HARMONi-2 (NCT05499390) trial compared ivonescimab with pembrolizumab as monotherapy in 398 patients with PD-ligand-1 (PD-L1)-positive (tumor proportion score [TPS] ≥1%) advanced non-small cell lung cancer (NSCLC) in China. In the primary analysis of HARMONi-2, progression-free survival (PFS) was significantly longer for patients treated with ivonescimab compared with pembrolizumab (hazard ratio [HR] 0.51 [95% CI 0.38-0.69]; one-sided P<0.0001) and was consistent across prespecified subgroups of patients with squamous and non-squamous histology. The objective of the current analysis was to further assess efficacy and safety outcomes by histology subgroup.

Methods: Patients enrolled in HARMONi-2 were adults with locally advanced or metastatic PD-L1-positive NSCLC without EGFR mutations or ALK translocations, who had not received previous systemic therapy. Patients were randomly assigned (1:1) and received intravenous ivonescimab 20 mg/kg or pembrolizumab 200 mg once every 3 weeks for up to 24 months; randomization was stratified by PD-L1 TPS expression, histology, and clinical stage. Efficacy and safety endpoints reported in the primary analysis of HARMONi-2 were evaluated in this subgroup analysis of patients with squamous and non-squamous NSCLC.

Results: The ivonescimab treatment group included 90 patients with squamous and 108 patients with non-squamous histology; the pembrolizumab treatment group included 91 patients with squamous and 109 patients with non-squamous histology. A further analysis has been conducted by PD-L1 TPS level for PFS. At the January 29, 2024, data cutoff, median follow-up was 8.7 months. The unstratified HR (95% CI) for PFS was 0.50 (0.33-0.76) in patients with the squamous histology and 0.55 (0.36, 0.84) in patients with the non-squamous histology. In the subset of patients with TPS 1-49%, the PFS HR was 0.51 (0.30-0.87) in patients with the squamous histology and 0.43 (0.21-0.88) in patients with the non-squamous histology, while in patients with TPS ≥50% the PFS HR was 0.43 (0.21-0.88) in patients with the squamous histology and 0.49 (0.25-0.96) in patients with non-squamous histology. In the ivonescimab treatment group, the overall response rate (ORR) in patients with the squamous histology was 53% and in patients with the non-squamous histology was 47% versus 31% and 45%, respectively, in the pembrolizumab treatment group. Serious treatment-related adverse events (TRAEs) occurred in 17 (19%) patients in the ivonescimab group versus 17 (19%) patients in the pembrolizumab group in patients with the squamous histology and 24 (22%) versus 15 (14%) patients with the non-squamous histology, respectively. Importantly, the rates of Grade ≥3 hemorrhage were similar in patients with squamous and non-squamous histology in the ivonescimab treatment group: 0 versus 2 (2%) patients respectively, and were similar to the rates seen in patients in the pembrolizumab treatment group: 1 (1%) versus 0 patients, respectively.

Conclusions: The analysis of histology subgroups from the HARMONi-2 study shows consistently numerically greater PFS benefit and response rate and a manageable safety profile for ivonescimab compared to pembrolizumab.

P1.11.84 Phase II Trial of Tislelizumab Combined With Anlotinib and 2-Cycle Chemotherapy as First-Line Treatment for Advanced NSCLC

W.J. Tang, X. qian, J. Luo, S. Lin, J. Xu, Y. Zhou, s. Liu, Y. Zeng, b. Li, H. Lin
The Second Affiliated Hospital of Hainan Medical University, Haikou/CN

Introduction: First-line chemo-immunotherapy has demonstrated remarkable survival benefits in advanced NSCLC. However, disease progression remains a persistent challenge, the median progression-free survival (PFS) is approximately 6~ 9 months. The design of this Phase II study, which combines immunotherapy, anti-angiogenic therapy, and short-course chemotherapy, aims to reduce the toxicity of chemotherapy while maximizing the synergistic anti-tumor effect that is greater than the sum of its parts, achieving a "1 + 1 + 1 > 3" effect.

Methods: This was a single-arm, single-center, exploratory study. Patients eligible for enrollment had previously untreated, histologically confirmed locally advanced NSCLC who were not amenable to curative surgery or radiotherapy (stage IIIB, IIIC) or metastatic (stage IV) NSCLC (per AJCC 8th edition). Patients received tislelizumab (200 mg, Q3W) plus anlotinib (12 mg, QD, d1-14, Q3W) and platinum-based chemotherapy for 2 cycles, then they continued maintenance therapy with tislelizumab plus anlotinib until disease progression, intolerable toxicity, or a maximum duration of 2 years was reached. The primary endpoint was progression free survival. Second endpoints included overall survival, object response rate, duration of response, disease control rate and safety.

Results: Between July 2021 and November 2023, a total of 21 patients were enrolled, with a median age of 64 years. Among them, 15 patients were non-sq NSCLC and 6 patients were sq-NSCLC. The majority of patients (90.5%) were at stage IV, and most patients (85.7%) had an ECOG PS of 1. As of March 7, 2025, the median follow-up duration was 24 months (range: 21-34) and the median treatment cycle for both tislelizumab and anlotinib was 10 (range: 3-32). The median PFS was 11.7 months (95%CI:8.5-NR), with 1-year and 2-year PFS rates of 46.6% and 35%, respectively. The median OS was not reached (95%CI:8.6-NR), and the 1-year and the 2-year OS rate were 60.2% and 50.1%, respectively. The ORR was 66.7%, DCR was 100%, and the median DOR was 7.6 months. The incidence rate of any-grade TRAE was 19.04%. No grade ≥3 TRAEs and irAE were observed.

Conclusions: Tislelizumab plus anlotinib and 2-cycle chemotherapy as first-line treatment for advanced NSCLC demonstrated promising efficacy with a tolerable safety profile. It might provide a new treatment strategy to prolong the survival benefits for advanced NSCLC patients.

Introduction: PD-1 and LAG-3 are distinct immune checkpoints upregulated in NSCLC that contribute to T-cell dysfunction. RELATIVITY-104 is a proof-of-concept, randomized, phase 2 study of first-line nivolumab + relatlimab (a human LAG-3-blocking antibody) + platinum-doublet chemotherapy (PDCT) versus nivolumab + PDCT in metastatic NSCLC. In Part 2 of the study, patients in the nivolumab + relatlimab + PDCT arm had higher ORR in the all-randomized population and a trend toward improved clinical benefit in the prespecified stratification factor subgroup of tumor PD-L1 expression ≥1%, which was further enriched in nonsquamous histology. The safety profile was generally manageable. Here, we report overall survival (OS), patient-reported outcomes (PROs), and exploratory translational analyses from Part 2 of RELATIVITY-104.

Methods: Adults with previously untreated stage IV/recurrent NSCLC, ECOG PS ≤1, and no targetable mutations were eligible. In Part 2, patients were randomized 1:1 (stratified by tumor PD-L1 expression, histology, and ECOG PS) to receive nivolumab 360mg + relatlimab 360mg + PDCT or nivolumab 360mg + PDCT, Q3W. ORR per BICR was the primary endpoint. Secondary endpoints included PFS per BICR, ORR/PFS by biomarker subgroups, and safety. Exploratory analyses were OS, translational analyses from the tumor, and PROs.

Results: With a median follow-up of 12.65 months (range, 0.03-28.42; database lock, 2 May 2025), PFS continued to favor nivolumab + relatlimab + PDCT versus nivolumab + PDCT in patients with tumor PD-L1 expression ≥1% and nonsquamous NSCLC (HR [90% CI], 0.68 [0.46-1.01]). In the all-randomized population, the OS HR (90% CI) was 1.04 (0.82-1.32). OS benefit was observed with nivolumab + relatlimab + PDCT in prespecified subgroups, including patients with tumor PD-L1 expression ≥1% and nonsquamous NSCLC (HR [90% CI], 0.60 [0.38-0.94]; table). In the nonsquamous NSCLC subgroup, relatlimab and nivolumab activity was linked to natural killer (NK) cells; high expression of a NK-cell-activating receptor gene signature in baseline tumors was associated with PFS and OS benefit. The safety profile of nivolumab + relatlimab + PDCT remained consistent with previous reports. PRO results will be presented.

Conclusions: Nivolumab + relatlimab + PDCT demonstrated a trend toward improved OS versus nivolumab + PDCT in the tumor PD-L1 ≥1% and nonsquamous NSCLC prespecified subgroups. These results from the first randomized phase 2 study of a LAG-3 blocking antibody-containing regimen in first-line metastatic NSCLC support further investigation of nivolumab + relatlimab + PDCT in the phase 3 RELATIVITY-1093 study.

Table. OS results from Part 2 of RELATIVITY-104

	Nivolumab + relatlimab + PDCT		Nivolumab + PDCT		OS HR (90% CI)

P1.17.01 Sociodemographic Factors in Access to Robotic-Assisted Oncologic Lung Resection, a United States (US) National Cancer Database Analysis

H. Reddington, I. Emmerick, J. Guart, Z. Ballinger, C. Briskin, D. Walter, A. Crawford, M.W. Maxfield, K. Uy, F. Lou
University of Massachusetts Chan Medical School, Worcester/MA/USA

Introduction: Robotic-assisted thoracoscopic surgery (RATS) has gained traction in the surgical management of non-small cell lung cancer (NSCLC), with potential benefits in postoperative pain and outcomes. However, equitable access to RATS remains unclear. We evaluated national patterns in RATS utilization and assessed whether sociodemographic disparities in access vary by geographic region in the United States (US).

Methods: We conducted a retrospective cohort study using the National Cancer Database (2010-2021), identifying adults with clinical stage I-IIIa NSCLC who underwent RATS or video-assisted thoracoscopic surgery (VATS). Patients with missing approach data were excluded. A multivariable logistic regression analysis using backwards selection was performed to examine the relationship between RATS approach and sociodemographic variables of interest. The model was fit with all variables with p<0.20 in the univariate analyses of patients with an MIS approach with <10% missing data. An interaction term between race and geographic location was included in the model to examine differing relationships between race and approach by region.

Results: Among 162,080 patients (62.8% VATS, 37.2% RATS), RATS utilization increased over time, surpassing VATS volume in 2019. Patients were primarily female (57%), white (82%), non-Hispanic (96%), with Medicare insurance (64%). Uninsured patients had lower odds of receiving RATS (OR=0.88, 95% CI 0.78-0.98, p=0.026), while Medicaid status showed no difference (OR=1.00, 95% CI 0.95-1.06, p=0.95). Patients in Medicaid expansion states had significantly lower odds of RATS (OR=0.80, 95% CI 0.77-0.83, p<0.001). Notably, racial disparities in RATS access varied by region: Black patients had lower odds of RATS in the South Atlantic and East North Central regions, but higher odds in East South Central and West South Central (OR 1.22) regions (Figure 1). Hispanic or Latino patients had lower odds in the East North Central region, but higher odds in New England and the Pacific.

Figure 1: Statistically significant findings from multivariable logistic regression predicting robotic approach among minimally invasive oncologic lung resections in the NCDB 2010-2021 (n=150,900), as compared to white non-Hispanic patients.

Conclusions: Access to robotic lung cancer surgery remains uneven across sociodemographic and geographic lines. These findings underscore the importance of addressing system-level barriers to advanced surgical technologies to ensure equitable access. As RATS continues to expand globally, ensuring equitable adoption will be critical to preventing downstream disparities in lung cancer care and outcomes.

P1.17.02 Socioecological Factors Associated With Lung Cancer Clinical Trial Enrollment: Real-World California Cancer Registry Data

. Arizpe[1], J. Nieva[2], T.A. Pickering[1], L. Liu[1], A.J. Farias[1]
[1]Keck School of Medicine of USC, Los Angeles/CA/USA ,[2]Keck School of Medicine, Los Angeles/CA/USA

Introduction: In the United States, less than 5% of participants in oncology clinical trials (OCTs) are from diverse race/ethnic backgrounds (i.e., Hispanic and Black), highlighting the need to identify modifiable socioenvironmental and clinical factors that may drive racial/ethnic disparities in OCTs participation. To fill this gap, we aimed to identify whether policy-, health system-, and patient-factors are associated with OCTs enrollment using data from a diverse population-based cohort of lung cancer cases in Los Angeles County, California.

Methods: We analyzed retrospective data from the California Cancer Registry/Los Angeles Cancer Surveillance Program between 2002-2021. Variables were operationalized: Outcome: OCT enrollment (not enrolled vs enrolled). Exposures: The policy- (Pre-2014 FDA plan to enhance the collection and availability of demographic subgroup data vs Post-2014, and COVID), Health system- (facility designated cancer center status: None vs All three, CoC-only, Multiple, NCI-only), and Patient-factors (Charlson comorbidity score [0 vs 1, 2, 3+], and insurance status [Private vs Medicaid, Medicare, Other]). Multivariable logistic regression model was used to explore these associations.

Results: Almost 1% (n=599/68,245) of our cohort was enrolled in OCT. Enrollees were mostly non-Hispanic White (NHW) (64.8%), Medicare-insured (60.3%), comorbidity-free (46.1%), and seeing at a CoC facility (62.1%). In unadjusted models, racial/ethnic minorities were less likely to be enrolled in OCT than NWH patients (Table). After adjusting for covariates, no statistically significant associations between race/ethnicity and OCT were found (Table). For the policy factor, we found that, during COVID, patients were 82% (OR=0.18, 95%CI: [0.10, 0.30]) less likely to be enrolled in OCT compared to the Pre-2014 FDA plan. For the health system, those that were seen at a CoC/NCI/NCCN facility were significantly more likely to be enrolled in OCT (All three=5.57[3.69, 8.33], CoC-only=5.64[4.29, 7.53], Multiple=8.12[5.67, 11.67], NCI=3.39[2.27, 5.02]) compared to those not being seen in any of those facilities. For our patient factor, we found an inverse association between comorbidity categories and OCT enrollment (1=0.72[0.59, 0.88], 2=0.51[0.37, 0.69], 3+=0.25[0.16, 0.37]). Similarly, compared to private insurance, having Medicaid was associated with a 53% (0.47[0.30, 0.72]) less likely to be enrolled in OCT, while Medicare was associated with a 92% (1.92[1.55, 2.38])increased likelihood of OCT enrollment compared to private insurance.

Conclusions: Using population-based data, our findings underscore that racial/ethnic disparities in OCT enrollment could be mitigated by addressing where individuals get cancer care, broadening comorbidity restrictions, and expanding cancer care research facilities in underserved areas.

Table: Multivariable association of policy-, and health system-, and patient-factors with the likelihood of oncology clinical trial enrollment among lung cancer patients from the California Cancer Registry/ Los Angeles Cancer Surveillance Program CSP (2002-2021)

P1.17.03 Stage Iv Nonsquamous Non-Small Cell Lung Cancer (NSCLC) Biomarker Testing Disparities and Outcomes: A Population-Based Stu

S. Singhal, T. Keegan, J. Riess, A. Parikh-Patel, B. Hofer, F.B. Maguire
University of California Davis, Sacramento/CA/USA

Introduction: Recognizing disparities in guideline-concordant EGFR and/or ALK biomarker testing is crucial to improve outcomes for patients newly diagnosed with stage IV nonsquamous NSCLC. This informs targeted interventions focused on populations least likely to receive biomarker testing, optimizing resource allocation. Despite the critical importance of biomarker testing, the rates and factors associated with testing is unknown.

Methods: This population-based cohort study used records from the California Cancer Registry to identify patients newly diagnosed with stage IV nonsquamous NSCLC between 2021 to 2022. Patients who received no systemic NSCLC treatment were excluded. Multivariable logistic regression was used to examine characteristics associated with biomarker testing. Multivariable Cox proportional hazards regression was used to compare overall survival (OS) between patients with and without biomarker testing.

Results: Among 4,530 identified patients, 1,430 (32%) had no EGFR and/or ALK biomarker testing reported. Patients residing in the lowest tertile of neighborhood socioeconomic status (SES) were less likely to receive biomarker testing (odds ratio 0.69, 95% confidence interval [CI] 0.57-0.84). Similarly, patients who were older, male, and had comorbid conditions were less likely to receive testing (Table). Patients without biomarker testing had a shorter median OS (11.3 versus 25.2 months, p<0.001) and increased hazard of death (hazard ratio (HR) 1.20, CI 1.09-1.33) than those with biomarker testing (Figure).

Conclusions: Nearly one-third of patients with NSCLC in this large cohort study did not receive guideline recommended biomarker testing and had significantly decreased OS. To our best knowledge, this is the largest study to date to define guideline-concordant biomarker testing disparities among patients with stage IV nonsquamous NSCLC. Targeted interventions to improve EGFR and/or ALK biomarker testing should focus on older adults, male patients, and those residing in low SES neighborhoods.

Table: Multivariable Logistic Regression of *EGFR* and/or *ALK* Biomarker Testing

Characteristic	Odds ratio (95% CI)	p-value

P1.17.04 Prioritizing Lung Cancer Screening in Middle-Income Countries: A Feasibility-Need Framework to Guide Implementatio

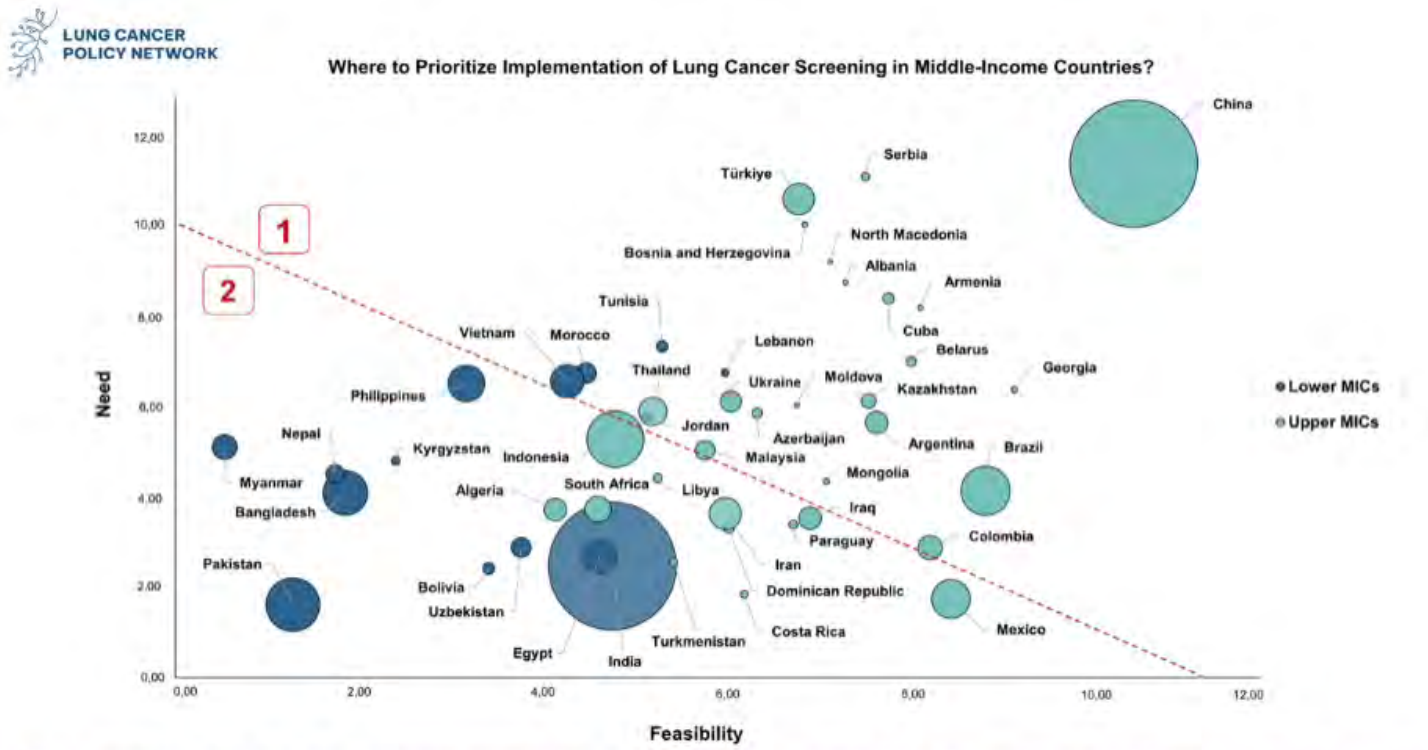
H. Petrovic[1,2], S. Schmidt[2], H. Wilcox[3]
[1]University of Lille, Lille/FR ,[2]Siemens Healthineers, Forchheim/DE ,[3]Lung Cancer Policy Network, London/GB

Introduction: A feasibility-need framework applied across 105 middle-income countries (MICs) identifies China, Vietnam, Türkiye, and several Balkan countries as top priorities for lung cancer screening (LCS) implementation. This data-driven, policy-focused approach integrates lung cancer burden and system readiness to determine where screening is both urgently needed and realistically feasible. Lung cancer remains the leading cause of cancer-related mortality worldwide, with 65.3% of deaths occurring in low- and middle-income countries. While most high-income countries are progressing toward reduced lung cancer mortality through national screening programs, many MICs face rising burdens from growing smoking rates and late-stage diagnoses. Low-income countries were excluded due to more urgent health priorities, including infectious disease control.

Methods: A comparative analysis of LCS need and feasibility was conducted using a weighted scoring system based on epidemiological and healthcare infrastructure indicators. Need scores were based on lung cancer mortality and incidence rates, five-year prevalence, cumulative risk of new cases, smoking prevalence, and life expectancy. Feasibility scores incorporated healthcare expenditure, CT scanner availability, number of physicians and radiologists, existing LCS studies, and GDP per capita, reflecting each country's capacity to execute screening. Countries with populations under 2 million and total scores below 2 (on a scale 1-10) were excluded due to insufficient justification for national screening efforts. Data were sourced from GLOBOCAN (IARC), WHO, JTO, LCPN, and national databases.

Results: Forty-six MICs met the inclusion criteria. Two focus clusters emerged: (1) High-Need, High-Feasibility; and (2) High-Need, Low-Feasibility. China was ranked highest in the overall readiness, but it still requires introduction of a national, structured screening program with guideline adherence, targeting the right risk groups. Türkiye, Serbia, Bosnia and Herzegovina, Albania, and North Macedonia exhibited the highest LCS need, but face a shortage of trained healthcare professionals needed to run screening programs. Vietnam, Kazakhstan, and Brazil show promise through active national research and piloting efforts. Indonesia and the Philippines demonstrated urgent need but limited feasibility, requiring foundational investments before introducing screening.

Conclusions: China, Vietnam, Türkiye, and the Balkan countries emerge as MICs where LCS could yield the greatest public health impact. However, workforce limitations, financing gaps, and lack of regulatory structures remain key barriers. Targeted investment and evidence-informed policy design are essential to unlock LCS potential in MICs. This feasibility-need framework can inform international and national NCD strategies and guide global collaboration. Ongoing qualitative interviews with national experts will further refine feasibility assessments and guide country-specific recommendations for LCS implementation.



*Data Note: This chart ranks lung cancer screening in middle-income countries based on need (lung cancer burden & screening demand) and feasibility (economic & infrastructure readiness). Bubble size reflects the population of each country. A diagonal line separates **High-Need, High-Feasibility Cluster (1)** and **High-Need, Low-Feasibility Cluster (2)**. Values on the axes are arbitrary and used for comparative visualization.*

P1.17.05 Evolution of Neoadjuvant Treatment for Non Small Cell Lung Cancer (NSCLC) in Brazil: An Analysis From the Brazilian Lung Cancer Registry

L.L. Lauricella[1], J. Gross[2], I. Rodrigues[3], L. Siyuan[4], M. Pimentel[5], P. D'Ambrósio[6], J. Salerno[7], R.M. Terra[1]
[1]Instituto do Cancer do Estado de Sao Paulo, Sao PAULO/BR ,[2]Hospital ACCamargo, sao paulo/BR ,[3]Hospital de Base da Faculdade de Medicina de Sao Jose do Rio Preto (FAMERP), Sao Jose do Rio Preto/BR ,[4]Hospital das Clinicas da Faculdade de Medicina de Ribeirao Preto, Ribeirão Preto/BR ,[5]Imperial Hospital de Caridade, Florianópolis/BR ,[6]Instituto do Cancer do Estado de Sao Paulo (ICESP), Sao Paulo/BR ,[7]Hospital Vila Santa Catarina, Sao Paulo/BR

Introduction: Neoadjuvant therapy has emerged as a promising strategy in managing locally advanced NSCLC, allowing tumor downsizing, early micrometastasis treatment, and potentially improved resectability. In 2022, the Brazilian regulatory agency approved nivolumab with chemotherapy for resectable NSCLC, marking the first immunotherapy approved for neoadjuvant use in Brazil. However, its routine availability in the public healthcare system remains limited and is currently restricted to clinical trials. This study aimed to analyze factors associated with neoadjuvant therapy use, treatment profiles, and survival outcomes in Brazil.

Methods: Data were drawn from the Brazilian Lung Cancer Registry, a multicenter database including patients undergoing lung cancer surgery since 2010. Patients with clinical stage IIA-IIIB (8th edition), excluding carcinoid tumors, considered eligible for neoadjuvant therapy per NCCN/ESMO guidelines were selected. Demographic and clinical variables were collected, and appropriate statistical tests were applied with $p<0.05$ as the significance level.

Results: Of 3,132 patients, 680 met inclusion criteria; 106 (15.58%) were excluded due to missing neoadjuvance data. Among the remaining, 84 (12.35%) received neoadjuvant therapy and 490 (72.06%) did not. Age, sex, race, ECOG, and comorbidity index were similar between groups. Neoadjuvant use was more common in the private sector (27.95% vs. 9.47%, $p<0.001$) and in advanced stages (IIIA/IIIB: 69.88% vs. IIA/IIB: 33.332%, $p<0.001$). Utilization increased markedly from 2020. Of treated patients, 61.45% received chemotherapy alone and 30.12% received chemoimmunotherapy. Mean surgical time was longer with neoadjuvant therapy (269.04 vs. 247.83 min, $p=0.076$), and robotic-assisted surgery was more frequent (22.62% vs. 10.25%, $p=0.006$). Histology also differed, with fewer squamous cell carcinomas and more "other" types in the neoadjuvant group ($p=0.037$). Downstaging was more common with neoadjuvance (52,56% vs. 35,15%, $p=0.049$). Survival did not differ significantly across stages IIA-IIIB.

Conclusions: Neoadjuvant therapy use in Brazil is still limited, with significant disparities between public and private systems. Patients treated in the private sector were nearly three times more likely to receive neoadjuvant therapy, reflecting unequal access to multimodal care. Its adoption increased notably after 2020, likely driven by emerging evidence and regulatory approval. Although associated with more downstaging and greater use of high-complexity techniques such as robotic surgery, no survival benefit was demonstrated. Differences in histology and surgical complexity suggest potential selection bias. These findings underscore the urgent need to reduce institutional and socioeconomic barriers to ensure equitable access to guideline-recommended care. Future studies should assess long-term outcomes and explore strategies to expand availability, particularly in the public health system.

P1.17.06 Who Gets a Biopsy? Disparities in Histological Confirmation and Survival Among Lung Cancer Patients

D. Urban[1,2], Y. Eshet[1,2], I. Vardi[1], R. Mano-Sitton[1], J. Bar[1,2], O. Globus[1]
[1]Sheba Medical Center, Ramat Gan/IL ,[2]Tel Aviv University, Tel Aviv/IL

Introduction: Histological confirmation is essential for lung cancer diagnosis and treatment selection, yet a subset of patients—particularly those with advanced disease—are diagnosed based solely on clinical or radiological suspicion. Some patients may present at an advanced stage and poor performance status, making a diagnostic procedure impractical. However, the rapid advancement of targeted therapies and immunotherapy for NSCLC makes histological confirmation increasingly critical for optimal treatment decisions. Some patients may be incorrectly excluded from the diagnostic process, thereby missing the opportunity for potentially life-prolonging therapies. This study aimed to analyze demographic and survival disparities among lung cancer patients based on whether a diagnostic confirmation was made.

Methods: We extracted all lung cancer cases from the SEER Research Data, 17 Registries (November 2022 submission), between 2000-2020. Patients were categorized as histologically confirmed or diagnosed solely by clinical/radiological suspicion. We examined demographic, socioeconomic, and geographic factors associated with non-confirmation. A subgroup analysis was conducted on metastatic patients. Kaplan-Meier estimates were used for survival comparisons, and chi-square tests evaluated correlations between categorical variables.

Results: Among 972,813 lung cancer patients, 78,913 (8.1%) were diagnosed without histological confirmation. This percentage decreased only slightly over time. Patients more likely to be diagnosed without confirmation were older, female, unmarried, lower-income, and living in rural areas (all $p < 0.001$). These disparities persisted in metastatic patients, where 7.4% (41,429 patients) lacked histological confirmation, including 6.0%, 10.9%, and 26.1% of patients aged 65-74, 75-84, and ≥85, respectively.

Patients in rural versus metropolitan areas (11.3% vs. 7.5%) and patients with an income <$50,000 vs >$75,000 (10.3% vs 7.4%) had higher rates of non-confirmation (both $p<0.001$).

Patients with a histologically confirmed diagnosis had significantly better survival (median survival: 11 months vs. 2 months, $p < 0.001$), including among metastatic patients (5 months vs. 1 month, $p < 0.001$). Among metastatic patients without histological confirmation, less than 25% survived beyond 3 months. The majority of patients died from lung cancer in both groups, further emphasizing that those without biopsy confirmation were not simply dying from comorbidities.

Conclusions: A significant proportion of lung cancer patients, including those with metastatic disease, do not undergo biopsy confirmation, raising concerns about missed treatment opportunities. The presence of socioeconomic and geographic disparities in biopsy rates suggests that some of these cases may be preventable. Additionally, the high early mortality rate in non-confirmed patients highlights the need for earlier recognition of symptoms and improved access to timely diagnosis. Efforts should focus on reducing disparities, enhancing diagnostic workflows, and ensuring all eligible patients receive histological confirmation for appropriate treatment selection.

P1.17.07 Comparing Baseline Characteristics of NSCLC Patients Receiving Radiotherapy in Real-World Practice and Clinical Trials

G. Walls[1,2,3], C. Cunniffe[2], G. Price[2], C. Faivre-Finn[1,2]
[1]Christie NHS Foundation Trust, Manchester/GB ,[2]University of Manchester, Manchester/GB ,[3]Queen's University Belfast, Belfast/GB

Introduction: NSCLC populations display diverse baseline patient characteristics (BPCs) due to differences in co-morbidities, risk factors and anatomical factors. Clinical trials typically recruit fitter patients who can better tolerate experimental treatment toxicities, limiting the generalisability of study findings. In the context of NSCLC radiotherapy, the characteristics of patient excluded from trials remain under-reported. This study compares the BPCs of patients treated at our centre with those reported in clinical trials and benchmarks them against data from other institutions.

Methods: BPCs of consecutive patients with NSCLC treated with curative-intent radiotherapy between 2013-2023 at a tertiary centre were extracted from a real-world data platform. Data included age, sex, ECOG PS, suitability for concurrent chemotherapy (CC), stage, and histological confirmation. BPCs were compared with published large (n=400+) institutional real-world series, and with eligibility criteria of phase II-III clinical trials evaluating conventional/mildly hypofractionated (CONV) and stereotactic (SABR) radiotherapy, published 2013-2023.

Results: Data from n=5,075 patients (n=3509 CONV, n=1566 SABR) from our centre were analysed. Median age 73 years; stage I 40%, stage II 27%, stage III 33%; CC received by 12% CONV. Eight institutional series were identified (two European, three US for CONV (n=3541), one European SABR n=7279). CONV patients were older at our centre compared with European and US cohorts respectively (age 72 vs 69 vs 66 years), less fit (ECOG 0-1 52% vs 77% vs 77%) and had lower rates of tissue diagnosis (81% vs 86% vs 100%). CC suitability was similar to Europe but lower than US (12% vs 10% vs 76%) (Table 1). SABR patients were less fit compared with the European cohort (ECOG 0-1 38% vs 74%) but had higher rates of tissue diagnosis (53% vs 34%), and similar age (75 vs 73 years). Twelve landmark trials were identified (eight CONV (n=2532), four SABR (n=453)) compromising: five European, five US, one Canadian, one Australian studies. At our centre, 31% patients met the eligibility for ≥1 trial. The eligibility was met by median 9.3% patients (IQR 9.3-16) for CONV trials, 42% (IQR 36.5-42) for SABR trials.

Conclusions: Pronounced differences in BPCs were observed between European and US real-world cohorts. A minority of European patients meet the eligibility for recent landmark clinical trials, primarily due to ECOG, tissue diagnosis and CC suitability. To enhance the generalisability and impact of future research, collaborative groups, funders, and industry partners should prioritise studies that are applicable to a broader patient population.

P1.17.08 Routine Self-Administration of a Nursing Demographic Survey to Patients Starting TKIs Identifies At-Risk Individuals

H. Vlahos, K. Rafique, L. Everest, F. Al-Agha, C. Brown, L.J. Zhan, A. Nafees, E. Tsang, S. Raptis, S. Barghout, K. Khan, D. Patel, B. Guiab, N.S. Clarkson, A. Burke, C. De Guia, P. Bradbury, F. Shepherd, A. Sacher, L. Eng, N.B. Leighl, G. Liu
Princess Margaret Cancer Centre, Toronto/ON/CA

Introduction: As oral tyrosine kinase agents (TKIs) become more prevalent as treatment in metastatic non-small cell lung cancer (NSCLC), it remains unclear the impact of out-of-pocket costs such as travel, affecting patients in a universal healthcare system. These burdens can act as a barrier to care as well has having impacts on quality of life. We piloted a nursing self-administered demographic questionnaire for outpatients starting EGFR TKI inhibitors.

Methods: Since 2020, we piloted a survey for patients with EGFR-mutant NSCLC starting first-line TKIs. It collected demographic data, out-of-pocket costs, travel distances, and number of clinic visits. Surveys were completed in clinic rooms before oncology appointments. This initial analysis focused on feasibility and descriptive data from baseline questionnaires in a single-centre CARMA-BROS study at Princess Margaret Cancer Centre (NCT04151342).

Results: FEASIBILITY: No concerns were raised around completing the survey. Language proved to be an issue in some patients, however, this was often mitigated by someone accompanying the patient. During COVID-19, patients were seen less often in clinic, leading to missing follow-up surveys. However, this had no impact on baseline analysis. Baseline completion rate exceeded 85%. DESCRIPTIVE ANALYSIS: In 178 patients with metastatic EGFR NSCLC, median age at diagnosis was 66 [inter-quartile range, IQR 57-74] years, 63% were female, 71% were never-smokers, 73% were of Asian ethnicity; 94% had adenocarcinomas; 81% were diagnosed initially in Stage IV. Socio-demographics showed 31% had annual household income of under CDN $30,000, while another 20% had income of CDN $30,000 to $59,000, only 20% declined to answer; 24% had a job change since diagnosis (retirement or stopping work). Out-of-pocket non-transport spending demonstrated that a proportion of individuals with more than CDN $80 of out-of-pocket spending due to their cancer was 30%. Of those, median annual spending was CDN $1580 [IQR: CDN $580 to CDN $3300]. The most common reasons for spending were for medications (17% of patients) and home renovations (6%). Travel to and from the cancer centre was assessed; 74% came by car, while 14% came by taxi and 11% came by public transit. The median distance travelled was 25km (IQR: 12km to 35 km). Median annual number of clinic visits was 22 [IQR: 12 to 40].

Conclusions: Patients completing this survey either independently or with caregivers was feasible. A minority of patients had either significant annual out-of-pocket spending costs and/or distance travelled to come to clinic for management of their EGFR TKI therapy. Over 50% had low annual household incomes of < CDN $50,000. These findings identify surveyed patients' logistical and financial burdens. Moreover, it identified individuals who may benefit from extra nursing and interdisciplinary support. With success of this pilot, the next implementation goals are to translate the questionnaire into multiple languages and share it digitally on a mobile app/tablet for patients/caregivers to complete at the initiation of TKIs. We aim to establish a formal process where this data is used to assess and support patient experiences as they begin EGFR TKI therapy.

P1.17.09 The Impact of Out-Of-Pocket Costs, Travel Distances and Clinic Visits on Quality of Life for Patients on TKIs

K. Rafique, H. Vlahos, L. Everest, F. Al-Agha, C. Brown, L.J. Zhan, A. Burke, C. De Guia, A. Nafees, E. Tsang, S.R. Raptis, S. Barghout, K. Khan, D. Patel, B. Guiab, N.S. Clarkson, N.B. Leighl, P. Bradbury, F.A. Shepherd, A. Sacher, L. Eng, G. Liu
Princess Margaret Hospital, Toronto/ON/CA

Introduction: The increasing use of oral tyrosine kinase inhibitors (TKIs) for metastatic non-small cell lung cancer (NSCLC) has raised important questions regarding the impact of barriers—such as travel distance, frequency of clinic visits, and out-of-pocket expenses—on patient quality of life within the universal healthcare system. Nurses can play a key role in mitigating these barriers through counseling, telehealth, and care coordination. We evaluated the association between out-of-pocket costs, travel distances, and number of clinic visits on health utilities, and EQ-5D-5L component questions in patients starting EGFR TKIs.

Methods: From 2020 onwards, we piloted a survey for patients with metastatic EGFR mutation starting on first-line EGFR TKI, that included: demographic data, out of pocket costs, travel distances, clinic visits, and EQ-5D-5L. Canadian-based health utilities were derived from EQ-5D-5L. Associations of out of pocket costs, travel distances, or clinic costs with health utilities of EQ-5D-5L questions were analyzed using Spearman's rho. This was a single center CARMA-BROS study analysis at Princess Margaret Cancer Centre (NCT04151342).

Results: In 175 patients with metastatic EGFR-mutated NSCLC, median age at diagnosis was 65 [inter-quartile range, IQR 57-74] years, 63% were female, 71% were never-smokers, and 73% were of Asian ethnicity; and 94% had adenocarcinomas; 82% were diagnosed initially in Stage IV. In terms of socio-demographics, 31% had annual household income of under CDN $30,000, while another 20% had income of CDN $30,000 to $50,000, and only 20% preferred not to answer; 24% had a job change since diagnosis (mostly retirement or stopping work). In terms of out-pocket non-transport spending, proportion of individuals with more than $80 of out-of-pocket spending due to then cancer was 30%. Associations between two barriers of care, i.e., annual out-of-pocket costs and number of clinic visits annually were each associated with health utility scores, and the majority of components that form the health utility, including a number of mild-to-moderate correlations with anxiety-depression and functional status (e.g. ability to perform usual activities, self-care, and mobility). Additionally, travel distance was not associated with overall health utility but was associated with pain and discomfort scores.

Conclusions: In TKI-treated patients, barriers-to-care were associated with quality-of-life, including symptoms and functional status aspects. This highlights the importance of nursing-led assessments to identify such barriers in these patients through nursing-based questionnaires. Next steps are to develop tools to support patients with these barriers, through the development of standardized social work, pharmacy, and nursing support triggers.

Table: Spearman's rho correlation of Barriers of Care and EQ-5D health utilities individual questions

			Health Utility Spearman's rho (95% CI)					
		n pts	Total Score	Anxiety and Depression	Mobility	Self-Care	Usual Activities	Pain and Discomfort

P1.17.10 Treating Without Guidelines: Management and Outcomes of Lung Cancer During Pregnancy

N.A. Guevara Rodriguez[1], N. Coreas[2], P. Budhathoki[3], P. Budhathoki[3], N. Pokharel[4], S. Shrestha[5], E. Shrestha[6], C. Olazagasti[7], E. Singhi[8], N. Florez[9]
[1]St. Louis University, Saint Louis/MO/USA ,[2]ISSS Oncology Hospital, San Salvador, El Salvador, San Salvador/SV ,[3]H. Lee Moffitt Cancer Center and Research Institute, Tampa/FL/USA ,[4]St. Francis Medical Center, Monroe/LA/USA ,[5]KIST Medical College, Nepal/NP ,[6]St Vincent's Medical Center, Bridgeport/CT/USA ,[7]University of Miami Sylvester Comprehensive Cancer Center, Miami/FL/USA ,[8]The University of Texas MD Anderson Cancer Center, Houston/TX/USA ,[9]Dana-Farber Cancer Institute, Dana-Farber Cancer Institute, Boston/MI/USA

Introduction: Lung cancer diagnosis during pregnancy is uniquely challenging due to the lack of treatment guidelines and the requirement for a careful balance between maternal treatment and fetal safety. However, with the increasing incidence of lung cancer in young women, we expect an increase in the number of lung cancer diagnoses during pregnancy. This systematic review evaluates clinical characteristics, diagnostic approaches, treatment timing, and maternal and fetal outcomes in these complex cases reported in the literature to date.

Methods: A comprehensive literature search of PubMed, Embase, and Scopus (1948-2024) identified 4,411 studies. After removing duplicates and irrelevant studies, 446 articles were screened, and 96 cases that met the inclusion criteria, specifically, the co-occurrence of pregnancy and lung cancer, were selected for analysis. Non-English studies were excluded. Variables included patient demographics, diagnostic modalities, cancer staging, treatment regimens, therapy timing, and outcomes. Statistical analysis was performed using Stata 15.1.

Results: The patients' median age was 33 years (SD ±4.97), ranging from 18 to 42 years. Advanced-stage disease (Stage III or IV) was diagnosed in 65% of cases, primarily through imaging, pleural fluid cytology, and histopathological evaluation. Chemotherapy regimens, such as cisplatin (29.5%) and paclitaxel (9.0%), were administered in 22.8% of cases during pregnancy, with a mean gestational timing of 21.8 weeks (SD ±10.4). Targeted therapies, including EGFR inhibitors (e.g., gefitinib and osimertinib), were used in 18% of cases, with 31.6% initiated postpartum. Surgery, predominantly lobectomy, was performed in a small number of cases (6.2%).Cancer stage was significantly associated with fetal outcomes ($p < 0.0001$), with Stage IV linked to higher rates of preterm delivery and pregnancy termination. The timing of chemotherapy was not significantly associated with fetal outcomes. However, granular data about chemotherapy administration is missing ($p = 0.25$). Tobacco use correlated with advanced-stage cancer ($p = 0.0006$), with 16% of tobacco users presenting at Stage IV. ALK fusions (32.9%) and EGFR mutations (21.4%) were the most common alterations seen in this cohort of pregnant patients with lung cancer. Live births were observed in 47% of cases. Regarding pregnancy outcomes, full-term deliveries (24.7%), preterm deliveries (29%), and pregnancy terminations (18%) were the most common outcomes. Fetal demise occurred in 1.08%, and in rare cases, 14.7% of fetal metastases were histopathologically confirmed.

Conclusions: Lung cancer during pregnancy, particularly in advanced stages, presents significant clinical challenges. Chemotherapy use in the second trimester and targeted therapies postpartum showed favorable maternal outcomes while minimizing fetal risk. These findings emphasize the importance of early diagnosis, tailored treatments, and the urgent need for standardized guidelines to manage these complex cases. Clinical Implications: This review underscores the critical need for a multidisciplinary approach involving oncologists, obstetricians, and neonatologists in managing pregnant patients with lung cancer. The collaborative effort of these professionals is essential in developing individualized treatment plans based on cancer stage, mutation status, and gestational timing, thereby optimizing maternal and fetal outcomes.

P1.17.11 Clinical and Molecular Characterization of Lung Cancer in Never-Smokers Identified Through an Incidental Nodule Program

J.F.d.P. Moura, P.P. Amorim, L.P. Lima, P.A. Sarmento, F.G.N. da Silva, D.V.F. De Carvalho, T.N. Beder, I.V. Secundo, F.M. de Gouveia, C.F. Jardin, F.A.C. Sarmento
Real Hospital Portugues de Beneficencia em Pernambuco, Recife/BR

Introduction: Lung cancer in never-smokers represents a growing clinical concern, now ranking among the top ten causes of cancer-related mortality in high-income countries, despite the absence of tobacco exposure. Early detection remains challenging, as no structured population-based screening exists for this subgroup. However, incidental pulmonary nodules detected through imaging studies offer a unique opportunity to diagnose these cancers at earlier stages. This study aimed to describe the clinical, morphological, and molecular profile of lung cancer in never-smokers diagnosed through an incidental nodule detection program.

Methods: We conducted a retrospective descriptive analysis of patients diagnosed with lung cancer via a pulmonary nodule detection program between January 2023 and December 2024. Only never-smokers were included. Variables collected included age, sex, clinical stage (0-4), nodule characteristics (density, border, size, and location), PD-L1 expression (<1%, 1-49%, ≥50%), and presence of oncogenic driver mutations (EGFR, ALK, KRAS, ROS1, BRAF, and others). Results labeled as "unknown," "not performed," or missing were grouped as "unknown."

Results: Of the 25,358 CT scans reviewed, 2,200 nodules were identified as suspicious for malignancy. A total of 237 patients enrolled in the nodule program, with 80 cases confirmed as lung cancer. Among these, 26 patients (32.5%) were never-smokers.

- Demographics: Mean age was 65.8 years (SD ± 16.9); 77% were female.

- Stage at diagnosis: Stage 0 (8%), Stage I (35%), Stage II (15%), Stage III (4%), Stage IV (38%).

Nodule characteristics:

- Density: solid (88%), ground-glass (8%), part-solid (4%)

- Border: regular (88%), irregular (12%)

- Location: left lower lobe (31%), right lower lobe (23%), right upper lobe (19%), left upper lobe (19%), middle lobe (8%)

- Mean size: 35.2 mm (SD ± 23 mm)

PD-L1 expression:

- <1%: 9 (82%)

- 1-49%: 2 (18%)

- ≥50%: 0 (0%)

- Unknown/not performed: 15 (58%)

Driver mutations:

- Detected in 13 (50%) patients

- Not detected: 5 (19%)

- Unknown/not performed: 8 (31%)

Conclusions: Our findings reinforce the value of incidental imaging in enabling earlier diagnosis of lung cancer in never-smokers. Despite the absence of targeted screening, this route shows promise in identifying cases at potentially curable stages. A significant proportion of tumors harbored actionable driver mutations, particularly among stage IV cases, underscoring the urgent need for improved access to molecular testing, even in early-stage disease. This study adds to growing evidence that lung cancer in never-smokers may constitute a distinct clinical and molecular entity, warranting tailored diagnostic and therapeutic strategies.

Introduction: Lung cancer is one of Australia's most common cancers and the leading cause of cancer death and cancer-associated burden of disease. Unwarranted variation in lung cancer care is described across Australia; interventions to systemically identify and address this are urgently required given the impending implementation of the government-funded National Lung Cancer Screening Program (NLCSP) in July 2025. The aim of the Lung Cancer Clinical Quality Data Platform (LUCAP) is to improve the safety and quality of lung cancer care through the utilisation of routine clinical data; this report describes findings over a twelve-month period.

Methods: Between September 2022 and December 2024, adult patients with suspected and confirmed thoracic malignancy referred to four tertiary hospitals in metropolitan Perth, Western Australia were recruited. Routine clinical data were prospectively captured, including demographics, appointment dates, investigations, multidisciplinary meeting (MDM) outcomes, and treatment modalities. Data were benchmarked against standards established by the Australian Optimal Care Pathway and national Clinical Quality Indicators (CQIs). Censor date was 09 February 2025.

Results: Over the project duration, 1261 participants were recruited, amongst which 1089 thoracic malignancies were diagnosed. There were 976 participants diagnosed with lung cancer; the median age was 71 years, 453 (46%) were female sex, and 320 (33%) reported current tobacco use. Table 1 summarises key CQIs over twelve months. No hospital met standards for timely lung cancer care, and additionally there was evidence of significant unwarranted variation between sites (CQIs 1, 3, 8). Variance in genomic testing rates was identified (CQI 6) and may reflect variable practice across public and private pathology providers. Rates of MDM discussion were universally high, however the quality of documentation varied (CQIs 11, 12, 13). Rates of treatment provision were high (CQIs 16, 17, 22, 23) for participants diagnosed with both early and late-stage disease.

Conclusions: There is evidence of unwarranted variation across the continuum of lung cancer care in metropolitan Perth; a minority of patients commenced treatment within target timeframes. Variation in the proportion of participants with complete genomic testing and timely PET/CT staging are of particular concern given the increasing complexity of thoracic oncology. Additional funding for staffing and infrastructure, as well quality improvement initiatives, will be required to fully realise the benefits of NLCSP implementation.

P1.17.13 Biomarker Testing Timeliness for Patients With Lung Cancer

B. Xiang, A. Aseem, T. Hill, N. Naffakh, M.M. Pasquinelli, F. Weinberg, R. Nguyen
University of Illinois Chicago, Chicago/IL/USA

Introduction: Complete and timely biomarker testing is a key step for selecting optimal treatment and clinical trial eligibility in patients with lung cancer. Despite this, racial and socioeconomic disparities in biomarker testing have been previously reported. This study evaluates biomarker testing timeliness for patients with lung cancer at an urban tertiary care safety-net hospital.

Methods: We conducted a retrospective review of next-generation sequencing (NGS) reports performed by an external vendor by tissue, blood, or both sampling methods for patients with a primary lung cancer at University of Illinois Hospital from December 2018 through March 2025. For patients who had multiple NGS tests done during their treatment course, only the initial NGS report was included in this analysis. Key variables were time from tissue or liquid biopsy to report, time from NGS test order to report, and the presence of an actionable molecular biomarker associated with an FDA approved therapy. Patient demographic and clinical data were obtained through retrospective review of the electronic medical record. Independent two-sample t-tests were performed to compare mean turnaround time from sample collection and order placement to NGS report. Association between race and NGS turnaround time were assessed using chi-square tests of independence.

Results: A total of 436 patients underwent NGS testing by either tissue (157; 36.0%), blood (78; 17.9%), or combination sampling (201; 46.1%). The cohort consisted of 50.9% male, 49.1% female, 64.7% Black, 22.8% White, 10.7% Hispanic, and 8.8% Asian. Histological distribution was 69.4% adenocarcinoma, 18.3% squamous cell carcinoma, 6.9% NSCLC-NOS, and 5.3% small cell carcinoma. Mean turnaround time from sample collection to NGS reporting was significantly shorter for liquid versus solid tumor (12.8 vs 38.6 days, $p<0.01$). Similarly, mean turnaround time from order placement to report was significantly shorter for liquid versus solid tumor (12.3 vs 21.1 days, $p<0.01$). There was no statistically significant association between race and turnaround time from sample collection to report for either solid tumor ($p=0.27$) or liquid biopsies ($p=0.52$). The distribution of turnaround times (≤14 days, 14-30 days, >30 days) did not differ significantly across racial groups. The percentage of patients with a molecular biomarker associated with an FDA-approved therapy by histology was 48.4% (adenocarcinoma), 25.8% (NSCLC-NOS), 8.7% (small cell carcinoma), and 7.6% (squamous cell carcinoma).

Conclusions: At our urban tertiary care safety-net hospital, liquid biopsy yielded significantly faster turnaround times than solid tumor biopsy for next-generation sequencing ($p<0.01$). While biomarker racial disparities have previously been reported, no significant racial differences were observed in the timeliness of biomarker reporting in our cohort. Nearly half of the patients with adenocarcinoma harbored actionable molecular alterations, highlighting the importance of comprehensive and timely molecular testing to guide precision oncology in diverse populations.

P1.17.14 Regional Disparities in Late-Stage Lung Cancer Outcomes in Sweden - Insights From Population-Based Data

A. Berglund[1], H. Vikman[1], E. Fernholm[2], A. Juhlin[3], D. Eek[4], N. Wilking[5]
[1]Epistat AB, Uppsala/SE ,[2]AstraZeneca, Stockholm/SE ,[3]AastraZeneca, Stockholm/SE ,[4]AastraZeneca, Gothenburg/SE ,[5]Karolinska Institutet, Stockholm/SE

Introduction: Lung cancer is often diagnosed late in the disease process, with detrimental impacts on patient outcomes. Using the recently launched VizCan platform with population-based cancer data offers a unique opportunity to improve lung cancer care through an enriched understanding of which factors that result in differences in cancer care. This study aims to examine potential regional differences in incidence, survival, and mortality in stage IV lung cancer.

Methods: VizCan is an interactive visualization platform open for everyone to use (https://vizcan.epistat.se). It includes 18 different cancer types. The study focuses on lung cancer and includes all patients identified via ICD-10 codes in the Swedish Cancer Registry (SCR) from 2014 onwards. Reporting to the SCR, managed by the National Board of Health and Welfare, is mandatory. Patient outcomes include age-standardized incidence, overall survival (OS), relative survival (RS), and age-standardized mortality.

Results: Between 2014 and 2022, a total of 37,206 patients were diagnosed with lung cancer. Almost 50% (n=18,437) were diagnosed in stage IV. The majority were older (mean age=71) and women (53%). The age-standardized incidence varied from 14 to 28 per 100,000 person years between different regions (Figure 1). The one-year OS and RS estimates differed between regions (26.7% to 37.2% for OS (Figure 2) and 27.0% to 37.2% for RS, respectively). Age-standardized mortality generally decreased over time, but also showed variations between regions. For instance, mortality in 2022 varied between 9 to 21 per 100,000 person years in different regions.

Conclusions: Regional differences exist in late-stage lung cancer incidence, survival, and mortality in Sweden, despite a declining mortality trend. The high proportion of patients diagnosed in stage IV underscores the need for earlier detection and improved access to timely and equitable care. Equal access to targeted interventions through regional quality improvements may help reduce disparities and enhance lung cancer outcomes

P1.17.15 Social Vulnerability and Survival Outcomes in Stages I-II Lung Cancer: A Predictive Nomogram-Based Analysis

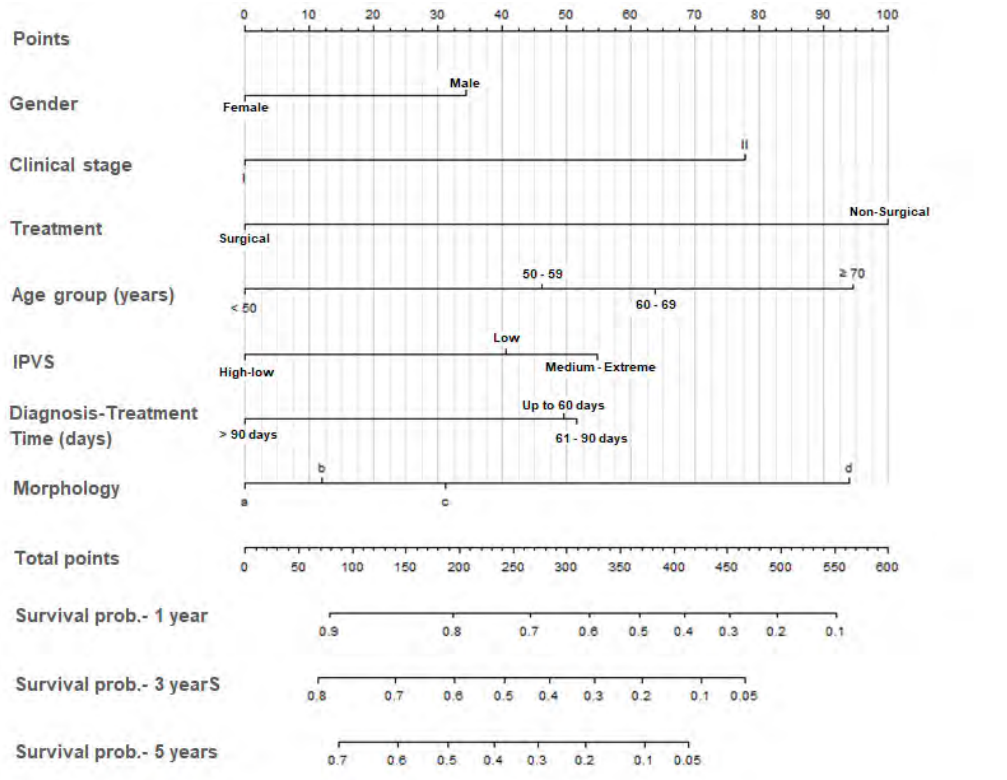
P.B. Costa[1], P. Duarte D'Ambrosio[1], R.M. Terra[2], P.M. Pêgo-Fernandes[1]
[1]Instituto do Coracao, Hospital das Clinicas HCFMUSP, Faculdade de Medicina, Universidade de Sao Paulo, Sao Paulo/BR ,[2]Instituto do Cancer do Estado de Sao Paulo, Faculdade de Medicina FMUSP, Universidade de Sao Paulo, Sao Paulo/BR

Introduction: Social vulnerability profoundly affects access to surgical treatment and survival outcomes in early-stage lung cancer. This study focuses on the development of a predictive nomogram that incorporates the Índice Paulista de Vulnerabilidade Social (IPVS -São Paulo Index of Social Vulnerability) as a critical determinant of disparities in patient management.

Methods: Data from 1,345 patients with stage I-II lung cancer diagnosed between 2000-2013 were analyzed. Kaplan-Meier survival analysis and Cox regression models assessed the impact of IPVS, treatment modality, and other clinical factors on survival. A nomogram was constructed using a multivariate Cox model to predict 1-, 3-, and 5-year survival probabilities, emphasizing PVS as a primary factor influencing surgical access and outcomes. The nomogram's predictive accuracy was evaluated using the C-index and AUC values.

Results: Patients in higher IPVS categories (IPVS 3) exhibited significantly lower rates of surgical treatment (p<0.001), with a mortality hazard ratio (HR) of 1.65 (95% CI: 1.34-2.04) compared to those in IPVS 1. Non-surgical treatment was the strongest predictor of mortality (HR=2.03, 95% CI: 1.76-2.35, p<0.001). Other significant factors included male gender (HR=1.25, 95% CI: 1.07-1.45) and age ≥70 years (HR=1.84, 95% CI: 1.45-2.31). The constructed nomogram incorporated IPVS, treatment modality, stage, age, gender, and histology, assigning a weighted impact to each factor. The nomogram (Fig. 1) demonstrated moderate predictive accuracy, with a C-index of 0.66 (95% CI: 0.64-0.68) and AUC values of 0.72, 0.74, and 0.73 for 1-, 3-, and 5-year survival, respectively. The tool revealed that higher IPVS levels correlated with delayed or absent surgical intervention, directly reducing survival probabilities.

Conclusions: The predictive nomogram highlights the Paulista Index of Social Vulnerability as a central determinant of disparities in surgical access and outcomes in early-stage lung cancer. By quantifying the impact of IPVS and other clinical factors, the nomogram serves as a valuable tool to guide targeted strategies for addressing inequities and improving access to life-saving surgical care.



DATABASE: 1,252 patients overall; 11 cases without IPVS information

P1.17.16 Racial and Ethnic Disparities in Receipt of Guideline Concordant Treatment for Early-Stage NSCLC in Los Angeles County

A.J. Farias[1], M.L. Gorbatov[1], A. Arizpe[1], L. Liu[1], E. David[2]
[1]Keck School of Medicine of USC, Los Angeles/CA/USA ,[2]University of Colorado Anschutz Medical Campus, Aurora/CO/USA

Introduction: Non-small cell lung cancer (NSCLC) is the leading cause of cancer mortality in California. Black patients experience the highest mortality rates (39 per 100,000) compared to Non-Hispanic White (NHW) (34 per 100,000), Asian/Pacific Islanders (A/PI) (23 per 100,000), and Hispanic patients (17 per 100,000). The most modifiable factor contributing to these differences is the receipt of guideline-concordant treatment (GCT), with surgical resection or radiation therapy recommended for all medically operable patients with stage I-II NSCLC. Despite rigorous clinical evidence supporting these guidelines, a higher proportion of Non-Hispanic Black (NHB) and Hispanic patients do not receive GCT compared to NHW patients. This study analyzed differences in receipt of GCT across racial and ethnic groups, leveraging data from a robust, population-based cohort of all early-stage NSCLC cases diagnosed in Los Angeles County.

Methods: Patients diagnosed with early-stage NSCLC (tumors <4cm, no lymph node involvement, and no metastases) between 2012-2022 were identified from the Los Angeles County Cancer Surveillance Program. Using a logistic regression model, we evaluated the association between race and ethnicity and receipt of guideline concordant treatment, adjusting for confounders including age, sex, socioeconomic status, insurance type, marital status, and tumor size. Outcomes were defined as receipt of GCT (surgery or radiation only), while non-GCT included no treatment or any combination of multiple treatments.

Results: A total of 2,857 patients with early-stage NSCLC were identified of which 57.3% were NHW, 8.9% were NHB, 14.2% were Hispanic, and 18.8% were A/PI. Patients with early-stage NSCLC were on average 69.6 years of age, majority female (63.2%), and had an average tumor size of 1.9 cm. While most patients (87.4%) received GCT, NHB patients had the highest proportion of non-GCT treatment (18.0%) followed by Hispanic patients (15.8%). NHB patients had significantly higher odds of not receiving GCT compared to NHW patients (OR: 1.54, 95% CI: 1.05-2.26; $p<0.05$). No statistically significant differences in GCT receipt were observed for A/PI or Hispanic patients compared to NHW patients. However, the disparities in non-GCT between Hispanic vs. NHW patients were largely explained in stepwise regression models by socioeconomic factors (crude OR: 1.59 [1.17-2.17] vs. fully SES-adjusted model OR: 1.26 [0.90-1.177]).

Conclusions: Addressing disparities in GCT for patients diagnosed with early-stage NSCLC is critical to improving survival outcomes. Future studies identifying factors influencing a patient's decision to receive GCT and a physician's decision to recommend and adhere to GCT guidelines is needed to understand the complexity of treatment decision-making.

P1.17.17 Financial Distress and Concerns Prior to Cancer-Directed Treatment Among Patients With NSCLC

A.I. Velazquez Manana[1], E. Trejo[1], M. Perales[1], L. Loftus[1], N. Dixit[1], M. Banegas[2]
[1]UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco/CA/USA ,[2]UC San Diego Moores Cancer Center, San Diego/CA/USA

Introduction: In recent years, significant progress has been made in the development of novel biomarkers and therapies for non-small cell lung cancer (NSCLC). However, the clinical benefits of this progress have not been equally distributed across all patient groups, partly due to adverse social conditions associated with poor health outcomes (i.e., health-related social needs). Previously published studies have shown that NSCLC survivors are more likely to have unmet supportive care needs, be unemployed, and experience financial hardship. Given the growing evidence of the associations of social adversity to poor health outcomes and the increasing costs of cancer care, we evaluated the prevalence of financial distress prior to the initiation of cancer-directed therapy among patients with NSCLC.

Methods: This multi-site prospective study enrolled adults with NSCLC initiating cancer-directed treatment into one of two cohorts: Cohort A enrolled patients with early-stage NSCLC receiving a curative intent treatment, and Cohort B enrolled patients with advanced NSCLC receiving noncurative intent treatment. Patients completed social needs and financial toxicity survey assessments prior to treatment initiation (baseline) and at 1, 3, and 6 months. Study enrollment is ongoing. We conducted an interim exploratory analysis of 56 patients enrolled in the study (aggregate of cohorts A and B) as of March 2025, who completed a baseline assessment. Data was summarized using descriptive statistics.

Results: Among 56 patients, 53.8% identified as female, 61.5% were aged 60-79, and 28.8% were aged 40-59. Regarding their NSCLC, 35.7% had early-stage disease and 64.3% had advanced disease. 34.7% of patients reported an annual household income of $24,999 or less. Prior to the initiation of cancer-directed therapy, 41.7% of participants reported experiencing financial concerns over the past week, and 38.3% expressed concerns about being able to take care of themselves. Over half (52.9%) of the patients reported not having enough money in savings, retirement, or assets to cover the costs of their treatment. Furthermore, 31.8% reported being “very much” concerned about potential financial challenges arising from their illness or treatment. Most patients (44.8%) reported dissatisfaction with their current financial status and 41.2% felt “not at all” in control of their financial situation. Participants commonly felt frustrated they couldn’t work or contribute as much as they usually did (14.9% quite a bit, 29.9% very much).

Conclusions: In this prospective cohort of patients with NSCLC, patients commonly experienced financial distress and concerns prior to the initiation of cancer-directed therapy. Early identification of financial concerns could help identify supportive resources for patients undergoing cancer treatment and help mitigate some of the adverse social conditions associated with poor health outcomes.

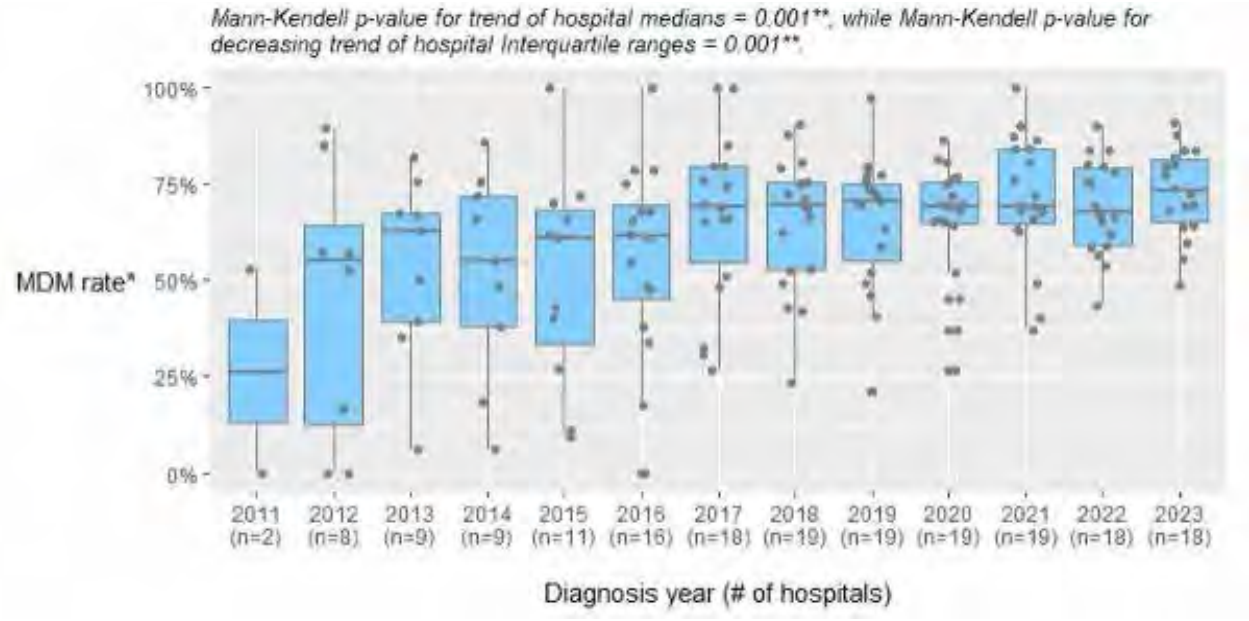
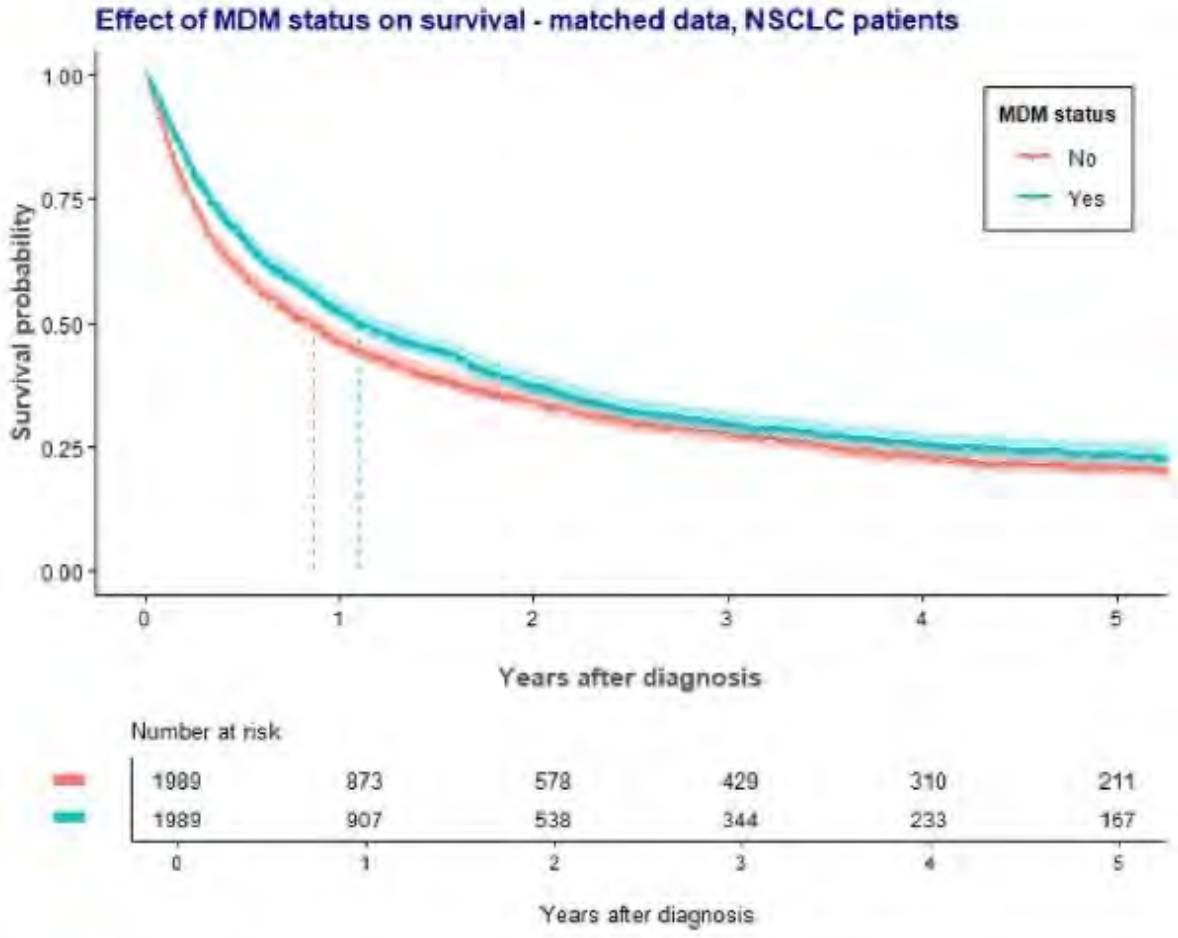
Introduction: Lung cancer is an heterogeneous and complex disease requiring multidisciplinary input for optimal management planning, with guidelines recommending all patients be discussed in a multidisciplinary setting. Multidisciplinary discussion (MDM) aims to enhance evidence-based management, improve treatment access and optimise complex management plans.

Methods: We aimed to assess the extent and impacts of MDM discussion in patients with lung cancer described by the Victorian Lung Cancer Registry (VLCR) from 2011-2024 in Victoria, Australia. We identified MDM presented and non-presented patients and assessed dependant management outcomes and survival impacts.

Results: 18,597 patients were included of whom 67% had evidence of presentation to a lung cancer MDM, with MDM presentation increasing from 59.1% to 80.6% during the study period Figure 1. MDM presentation was associated with significantly higher levels of provision of Guideline Concordant Treatment (GCT) in NSCLC (52.9% vs 42.3%, p<0.001), non-GCT and lower levels of no treatment (13.4% vs 24.6%, p<0.001). Modifiable factors which may increase MDM presentation included higher age, stage IV disease and treatment in a private hospital. Propensity matched survival analysis in NSCLC revealed a median survival of 1.1 years (1.0-1.3 years, p<0.001) for MDM presented vs non presented individuals 0.86 years (0.76-0.94), providing a 12% reduction in mortality hazard (HR 0.88(0.82-0.95), p<0.001) Figure 2.

Conclusions: Clinical Quality Registries enable assessment of the appropriateness and effectiveness of healthcare implementation in population-based complex disease domains and inform quality improvement initiatives within learning health systems. MDM presentation increased by 20% during this study period providing significant management optimisation and survival advantage





MDM status	N	1 year survival (95% CI)	5 year survival (95% CI)	Median survival, years (95% CI)	Hazard ratio (95% CI)	P-value
No	1,989	46.4% (44.2-48.6)	20.9% (19-22.9)	0.86 (0.76-0.94)	Ref.	Ref.
Yes	1,989	52.5% (50.3-54.9)	23.4% (21.2-25.8)	1.1 (1.0-1.3)	0.88 (0.82-0.95)	<0.001***

P1.17.19 Impact of Race and Ethnicity on the ENGAGE-Derived Lung Cancer Screening Recommendations: Implications for Risk Assessment

M. Eghbalizarch[1], C.M. Tammemagi[2], S.M. Mousavi Janbeh Sarayi[1], S. Ishizawa[1], R. Meza[3,4], I. Toumazis[1]
[1]The University of Texas MD Anderson Cancer Center, Houston/TX/USA ,[2]Brock University, St. Catharines/ON/CA ,[3]BC Cancer Research Institute, Vancouver/BC/CA ,[4]University of British Columbia, Vancouver/BC/CA

Introduction: The ENGAGE framework optimizes lung cancer screening based on age, sex, and smoking related risk factors, for ever-smoked individuals at a personalized-level. The inclusion of race and ethnicity in risk prediction models is controversial. We adapted the PLCOm2012 risk model and integrated it into ENGAGE to evaluate the influence of race and ethnicity on the ENGAGE-derived lung cancer screening schedules.

Methods: We developed and validated three versions of Cox proportional hazards regression models for lung cancer risk differing by the levels of race and ethnicity included (6-race, 3-race, no-race) and one model to predict death from causes other than lung cancer using data from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO). The developed risk models incorporate all PLCOm2012 covariates but converted smoking intensity and body-mass index (BMI) from continuous to categorical variables. The competing causes of death model includes all PLCOm2012 covariates except family history of lung cancer plus sex, diabetes, cardiovascular disease, stroke, and hypertension. We integrated these risk models into ENGAGE and generated personalized screening schedules for the National Lung Screening Trial (NLST) participants who were randomized in the low dose computed tomography (LDCT) arm and were adherent to annual screening. We compared the performance of ENGAGE across the different versions of the risk models (6-race PLCOENGAGE2025, 3-race PLCOENGAGE2025, no-race PLCOENGAGE2025) and the original ENGAGE that uses the Bach risk model, in terms of the number of screen-detected cases, number of screening exams, and number of false-positive results.

Results: The PLCOENGAGE2025 models demonstrated good and comparable discrimination, calibration, and validation in both PLCO and NLST data. Screening schedules derived from ENGAGE performed better when based on PLCOENGAGE2025 compared to the Bach risk model. The ENGAGE version utilizing the Bach model reduced screening exams by 81% and false-positive results by 84%, while delaying screen-detected lung cancer diagnoses by 2.8% relative to the NLST results. ENGAGE-derived schedules based on the PLCOENGAGE2025 race-specific models outperformed those using the PLCOENGAGE2025 no-race model for Black individuals, resulting in more screen-detected cases and higher mortality reduction (Figure 1).

Conclusions: Incorporating race and ethnicity into lung cancer risk models enhances the effectiveness of screening in a mixed-race population which justifies its consideration in risk prediction models. ENGAGE-derived schedules maintained comparable effectiveness to annual screening despite reducing the number of screening exams and false-positive results.

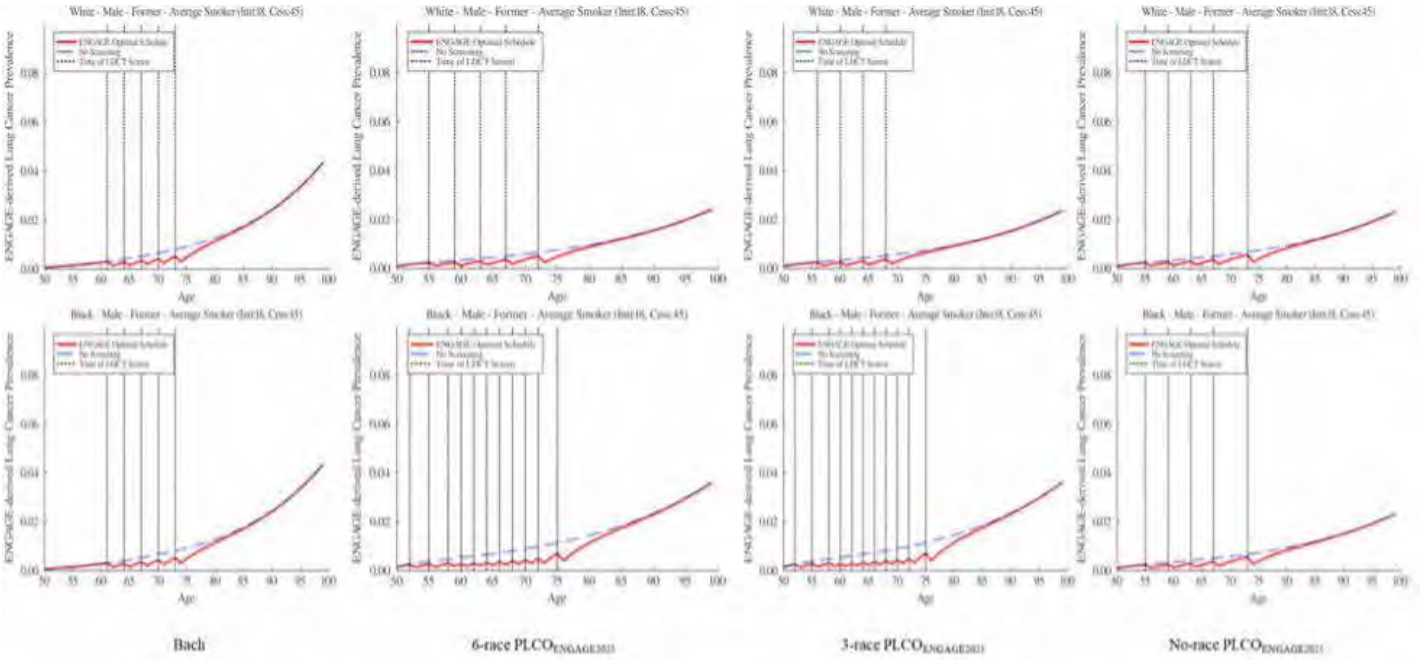

Figure 1. ENGAGE lung cancer screening schedule for a male former average smoker with overweight, some college education, no chronic obstructive pulmonary disease, no family history of LC, no personal history of cancer, and no comorbidities. The first row represents the Non-Hispanic White population, and the second row represents the Non-Hispanic Black population. Risk models considered include the 6-race PLCO$_{ENGAGE2025}$, 3-race PLCO$_{ENGAGE2025}$, no-race PLCO$_{ENGAGE2025}$, and Bach model.

Introduction: People living in rural and remote communities have higher smoking rates and lung cancer diagnoses than their metropolitan counterparts. Tobacco use is a significant risk factor, contributing to approximately 90% of lung cancers in males and 65% in females. Additionally, age-standardised mortality rates for lung cancer increase with geographical remoteness. People with cancer from rural and remote areas often experience delays in diagnosis and treatment. Accessing infrastructure such as CT imaging and radiation therapy can pose a challenge in these regions, impacting timely and effective lung cancer diagnosis and care. Addressing these disparities and inequities in rural and remote areas requires dedicated research. This abstract presents an overview of the Equitable Cancer Outcomes across Rural and Remote Australia (ECORRA) program, which aims to improve cancer outcomes through targeted strategies and interventions.

Methods: The ECORRA program consists of three funded projects in progress conducted across several states of Australia. We will describe: 1) ECORRA Trial: A national stepped-wedge trial to embed a co-designed implementation package to reduce time to diagnosis and time to treatment for people with cancer in rural and remote communities; 2) ECORRA Optimal Care Pathway: The development of a rural and remote specific Optimal Care Pathway, a nationally endorsed standard for the delivery of timely, quality care; which will complement the existing tumour Optimal Care Pathways such as lung cancer; 3) ECORRA Victoria: A statewide survey to identify and compare the predictors of delays to diagnosis and treatment between rural and metropolitan Victorians. All projects are active and include people with lung cancer.

Results: This program of work represents strong partnerships across academic institutions, clinicians, health services, policymakers and community organisations. A consumer advisory group of 18 people from rural and remote areas has been appointed to contribute across the program. A fit for purpose governance structure has been established and endorsed, with national site visits underway. Responses to four public government consultations have been submitted and PhD projects aligned to the program have commenced. Ethical requirements for all necessary components of the program have been lodged and approved. For the ECORRA Trial, national quantitative surveys and qualitative interviews are underway to inform development of the implementation package, with 60-100 interviews with a diverse range of health care professionals providing cancer care and consumers to be completed by the time of this presentation. Over 30 professionals and people with lived experience of cancer have informed the first draft of the Optimal Care Pathway, which will undergo national public consultation later in 2025.

Conclusions: The ECORRA program represents an interdisciplinary investment to reduce cancer inequities across rural and remote communities through integrated research and policy approaches. Supported by both state and federal funding, the program aims to drive meaningful improvements in cancer care. Key results relevant to lung cancer treatment and outcomes will be presented, and the next steps will be outlined. Approaches to scalability and sustainability will be presented, to drive lasting impact for people affected by lung cancer from rural and remote areas.

P1.17.21 Gender Disparities in Remote Patient Monitoring: Analysis From 973 Lung Cancer Patients Treated Across 42 Sites in France and Belgium

C. Parisi[1], L. Greillier[2], C. Audigier-Valette[3], J. Pluvy[4], D. Planchard[5], S. Deshayes[6], H. Pegliasco[7], A.R. Ferreira[8], C. Ferté[9], M.A. Franzoi[5], A. Yazigi[9], M. Autheman[9], C. Tissot[10], D.L. Ferreira[6], I. Vaz-Luis[5], B. Besse[5], F. Barlesi[5]
[1]Gustave Roussy, Villejuif, France/FR ,[2]Assistance Publique Hopitaux de Marseille (AP-HM), Marseille/FR ,[3]Centre Hospitalier Toulon Sainte-Musse, Toulon/FR ,[4]Hôpital Nord - APHM, Marseille/FR ,[5]Gustave Roussy, Villejuif/FR ,[6]CHU de Caen, Caen/FR ,[7]Hôpital Européen Marseille, Marseille/FR ,[8]Resilience and Católica Medical School, Universidade Católica Portuguesa, Paris/FR ,[9]Resilience Care, Paris/FR ,[10]Hôpital Privé de la Loire, Saint-Étienne/FR

Introduction: Gender disparities in cancer care and outcomes are increasingly evident, affecting incidence, treatment access, and survival. Multiple phase III trials have established remote patient monitoring (RPM) with ePROs as a standard, improving morbidity and quality of life. RPM also offers a unique opportunity to assess baseline social determinants of health (SDOH) and symptom burden. This study examines gender-based differences in RPM use and outcomes among lung cancer patients.

Methods: The RPM process included medical prescription, weekly symptom monitoring (PRO-CTCAE), and alerts to healthcare providers (HCP) for severe or worsening symptoms. Data from 973 lung cancer patients treated at 42 sites in France and Belgium between January 2022 to December 2024 were analyzed. Gender-specific differences in demographics, tumor characteristics, treatment modalities, symptoms and social determinants of health (SDOH) were evaluated.

Results: Among 973 lung cancer patients, descriptive statistics were as follows: 44% female (F) and 56% male (M), mean age 65.1 (F) vs. 66.4 years (M) (p = 0.05); metastatic disease in 67.9% (F) vs. 61.5% (M); 49.8% of patients had non-oncogene-addicted NSCLC, 37.8% had oncogene-addicted NSCLC and 8.7% had a SCLC. Unfavorable SDOH were similar across groups except alcohol consumption frequency (F:12.7% vs. M: 29.5% p<0.001). Female exhibited higher adherence to weekly questionnaire (F: 84.3% vs. M:81.5%, p<0.001) and shorter time to process them (median response time (hours) [Q1-Q3] (M: 10.6 [1.4,57.2], F: 9.2 [1.3,49.3], p=0.004). At baseline, female patients experienced higher symptoms burden (PROs grade ≥ 3 symptoms) including anorexia, nausea, vomiting, diarrhea, constipation (F: 45.7% vs. M: 34.5%, p<0.001) and unfavorable physical function related symptoms including pain, performance status (PS), fatigue (F: 59% vs. M: 46.9%, p<0.001). Female patients had higher rates of symptom improvement after alerts (≥ 1 grade reduction, PRO-CTCAE of 93.8% (M) vs. 97.5% (F), p=0.032) compared to males. Imbalances in symptom burden appeared mitigated at 12 weeks, with non-significative remaining differences.

Conclusions: Female patients showed a higher burden for digestive symptoms and unfavorable physical function. Female patients exhibited higher degree of symptom improvement following RPM alerts, suggesting that baseline differences could be alleviated by RPM. Gender-specific differences underscore the need for tailored RPM strategies to ensure more equitable clinical outcomes.

P1.17.22 Concordance of HER2 Protein Overexpression by IHC and ERBB2 Gene Amplification by NGS in Lung Cancer

S. Mehta[1], S. Yeramaneni[1], K. Wang[1], M.S-A. Woo[1], A. Ashtekar[1], A.H. Newell[1], A. Shah[2], S. Zaara[2], L.C. Lee[2], J.A. Marks[3]
[1]Daiichi Sankyo, Basking Ridge/NJ/USA ,[2]AstraZeneca, Gaithersburg/MD/USA ,[3]Dana- Farber Cancer Institute and Harvard Medical School, Boston/MA/USA

Introduction: Recently approved HER2-directed antibody drug conjugate - trastuzumab deruxtecan (T-DXd) for HER2+ solid tumors specifically targets the HER2 protein on the surface of cancer cells. Broad-based, next generation sequencing (NGS) testing is standard for those with advance non-small cell lung cancer (NSCLC). While there is a known strong correlation between HER2-overexpression (OE) and ERBB2 gene amplification (amp) in other malignancies such as breast cancer, little is known of the correlation in lung cancers. Moreover, if only ERBB2-amp is assessed by NGS without evaluation for HER2-OE by IHC, patients may be misidentified and not be able to receive appropriate treatment for HER2-OE advanced NSCLC such as T-DXd. This study aims to assess the concordance between HER2-OE and ERBB2-amp, among lung cancer patient samples evaluated simultaneously by IHC and NGS tests.

Methods: We examined tissue samples tested by Neogenomics Laboratories of individual lung cancer patients who received the NeoTYPE® Lung Tumor (NTP) profiling between May 2023-June 2024. As part of NTP, HER2-OE was assessed by IHC (clone 4B5) using ASCO/CAP breast scoring algorithm. HER2-OE criteria was met if samples were IHC 2+/IHC 3+. ERBB2-amp was obtained by NGS and considered positive if the copy number variant gain was ≥2.8 (qualitative assay with 88% sensitivity and 82% specificity). The proportion of samples with overlapping HER2 IHC and ERBB2 NGS test results were reported. The association between HER2 IHC and NGS ERBB2-amp tests was examined using chi-square and concordance using spearman's rank correlation tests.

Results: Of the 2,960 samples included, 28.2% (n=836) met the HER2-OE criteria and 22.2% (n=657) tested positive for ERBB2-amp (Table). An overlap between HER2-OE and positive ERBB2-amp was observed in only 10.0% (n=294) of the samples. A statistically significant association was found between the HER2 IHC and ERBB2-amp test results (p-value<0.001), with a trend toward increasing rate of positive ERBB2-amp from IHC 0 to IHC 3+ (correlation coefficient 0.19, p-value<0.001). However, ERBB2-amp was negative among 66.6% of IHC 2+ (529/794) and 31.0% of IHC 3+ (13/42) samples.

Conclusions: The concordance between HER2-OE and positive ERBB2-amp was observed only in about one-tenth of the samples. Nearly one in three samples from the IHC 3+ and two out of three samples from the IHC 2+ group were missed if patients were only tested with NGS. These findings highlight the importance of incorporating HER2 IHC into routine diagnostic workup for lung cancer patients to accurately identify patients eligible for HER2-directed therapy such as T-DXd.

P1.17.23 Role of Lung Microbiome on Precise Diagnosis of Patients With Checkpoint Inhibitor Pneumonia: Result From a Prospective Cohort Study

Z. Zhou, J. Lin, J. Li, X. Huang, L. Liu
Southern Medical University Nanfang Hospital, GuangZhou/CN

Introduction: Checkpoint inhibitor pneumonia (CIP) is a lethal immune-related adverse event in cancer patients receiving immunotherapy. This study aims to characterize the lung microbiome in CIP patients and evaluate its diagnostic potential.

Methods: In a prospective clinical trial (NCT06192303), bronchoalveolar lavage fluid samples (BALF) were obtained from 38 patients presenting clinical symptoms and radiographic evidence of pneumonitis following immunotherapy. The cohort included 14 cases of pure-type CIP (PT-CIP), 14 cases of mixed-type CIP (MT-CIP), and 10 cases of pulmonary infection (PI). Metagenomic next-generation sequencing (mNGS) of BALF was employed to delineate the lung microbiota profiles. Using linear discriminant analysis effect size, we discerned characteristic microbiota among the three groups and further explored the associations of signature microbiota with host immune-inflammatory markers. Functional enrichment analyses revealed potential metabolic reprogramming and differences in biological functions between CIP and PI patients. Finally, leveraging four machine-learning models, we ascertained the value of BALF microbiota profiles in diagnosing CIP.

Results: The composition of lung microbiota differed significantly between CIP and PI patients. Microbial taxa, such as Porphyromonas, Candida, Peptostreptococcus, Treponema, and Talaromyces, exhibited distinct abundance patterns across the three groups. Correlation analysis revealed a significant positive correlation between Candida abundance and host immune-inflammatory markers, such as neutrophil-lymphocyte ratio, platelet-lymphocyte ratio, monocyte-lymphocyte ratio, systemic immune inflammation index, while Porphyromonas demonstrated negative correlation. Compared to the PT-CIP patients, the lung microbiota of PI patients exhibited a more diverse biological and metabolic profile. Additionally, machine learning models based on BALF microbiota profiles could accurately diagnose CIP, with the decision tree model showing the best diagnostic performance (AUC: 0.88).

Conclusions: Our study unraveled the characterization of the lung microbiota profiles across distinct CIP subtypes and established a diagnostic model for CIP based on the decision tree. These findings emphasize the value of BALF mNGS in improving the diagnosis of CIP.

Introduction: Biomarker testing has become essential for non-small cell lung cancer (NSCLC), but optimal testing is not yet performed universally, nor is the pathway to achieving this clear. We used mixed methods to explore not only testing practices but also associated workflows/processes in diverse settings across the United States.

Methods: We utilized U.S. data from the 2024 IASLC Global Survey (IGS) on Biomarker Testing and structured interviews with thoracic oncology providers to understand current U.S. practices and their context. An interim analysis of the first 15 interviews was performed in NVivo 14 to identify both common themes and unique practices.

Results: There were 287 IGS U.S. respondents from 39 states and 15 interview participants, representing 11 sites across 8 states. Both IGS and interview data included majority academic centers (64% and 62%, respectively), but interview data included more community sites (16% versus 31%). Oncologists predominated in IGS (49%), whereas thoracic surgeons comprised the majority of interviewees (53%). Table 1 summarizes participant characteristics and key findings regarding current practices, workflows, and barriers to best practice testing. Biomarker practices varied widely, particularly for early-stage testing. IGS respondents universally reported cost among the top 3 barriers, compared to only 3 interview participants. While most interviewees reported no cost considerations in their biomarker testing decision-making, they did commonly report delays due to the Medicare “14-day rule” (non-reimbursement for in-patients) and need for universal insurance coverage, both ultimately cost-related, as barriers. Turnaround time (TAT) was identified as a top 3 barrier in all IGS groups except for pathologists, and among interviewees, who noted variability in workflows, lack of defined role responsibilities/ownership, and bottlenecks due to staffing shortages as causative factors. Although 50% of IGS respondents reported reflex testing, including 53% of community, only 27% of interview sites and none of the community/other sites had reflex protocols. Interestingly, sites with reflex testing frequently identified it as a facilitator and/or target for improvement nationally, and yet only 33% of participants at sites without reflex did so.

Conclusions: Cost, TAT, and tissue remain the most important barriers to biomarker testing in the U.S. Although most key themes were similar between interview and IGS U.S. results, the in-depth interviews uncovered several important differences and revealed significant heterogeneity in practices and needs. Additionally, these findings suggest the need for greater assessment in real-world settings to identify and implement tailored solutions.

type (site)	specialty	who & % tested†	NGS utilization	who orders	reflex status	TAT	barriers/targets for improvement

P1.17.25 Cost-Effectiveness of Initial Pan-TRK IHC Followed by RNA-NGS for NTRK Fusion Detection in Patients With NSCLC in China

Y. Han[1], S. Li[2], W. Chen[3]
[1]Shanghai Chest Hospital, shanghai/CN ,[2]The First Affiliated Hospital of Zhengzhou University, Zhengzhou/CN ,[3]Fudan University, Shanghai/CN

Introduction: Neurotrophic tyrosine receptor kinase (NTRK) gene fusions are oncogenic drivers in various adult and pediatric tumors, including approximately 0.24% of non-small cell lung cancer (NSCLC) cases. NTRK testing is recommended for metastatic NSCLC to guide targeted therapy. Various detection methods exist, each with differing costs and effectiveness.

Methods: A decision tree model was constructed from a health system perspective in China to simulate patients with NSCLC and evaluate the costs and health outcomes of next-generation sequencing (NGS) and pan-TRK immunohistochemistry (IHC) followed by RNA-NGS confirmation (pan-TRK IHC+RNA-NGS) . Diagnostic performance data were sourced from literature and validated by pathologists and clinicians. Data on clinical efficacy, treatment costs, and utility for progression-free survival (PFS) were obtained from open databases and literature. Expert interviews provided turnaround time and testing costs. The time horizon included the duration of NTRK testing and the PFS period associated with the medication. Both one-way and probabilistic sensitivity analyses were conducted to assess the model's robustness.

Results: The analysis considered two scenarios based on regional variations in NTRK testing in China: Scenario1:For 10,000 patients with NSCLC, the NGS testing alone produced 5278.9 life years (LY) and 3750.6 quality-adjusted life years (QALY) at a total cost of $61,811,372, whereas the pan-TRK IHC +RNA-NGS testing strategy yielded 5280.2 LYs and 3751.7 QALYs at a lower total cost of $43,944,162.Scenario 2: Assume that the proportion of driver-gene-negative NSCLC patients (where the driver genes include those targeted by drugs approved in China: EGFR, ALK, ROS1, BRAF V600, RET, and MET exon 14 skipping) is 40%, for 10,000 driver-gene-negative NSCLC patients, the pan-TRK IHC+RNA-NGS testing strategy demonstrated an incremental benefit of 3.21 LYs and 2.78 QALYs, while reducing costs by $17,743,631. In both scenarios, the pan-TRK IHC+ RNA-NGS was dominant, offering higher LYs and QALYs and lower costs than NGS alone. Sensitivity analysis confirmed the robustness of the results. Moreover, the average wait time per patient for pan-TRK IHC+RNA-NGS was reduced by 11 days.

Table1: Cost-Effectiveness Analysis Results-Scenario1

	Testing	Total Cost(USD$)	Effectiveness (LYs)	Effectiveness (QALYs)	Incremental cost ($)	Incremental QALYs	ICER (Cost/QALY)
10,000 NSCLC patients	NGS	$61,811,372	5278.9	3750.6			
	pan-TRK IHC+RNA-NGS	$43,944,162	5280.2	3751.7	-$17,867,210	1.11	pan-TRK IHC +RNA-NGS was dominant

Table2: Cost-Effectiveness Analysis Results-Scenario2

	Testing	Total Cost (USD$)	Effectiveness (LYs)	Effectiveness (QALYs)	Incremental cost ($)	Incremental QALYs	ICER (Cost/QALY)
10,000 driver-gene-negative NSCLC patients	NGS	$62,541,935	5303.6	3772.0			
	pan-TRK IHC+RNA-NGS	$44,798,305	5306.8	3774.7	-$17,743,631	2.78	pan-TRK IHC +RNA-NGS was dominant

Conclusions: Initial pan-TRK IHC testing followed by RNA-NGS confirmation for positive results is the preferred strategy for detecting NTRK fusions in patients with NSCLC in China. This approach provides better economic value and clinical outcomes than NGS testing alone.

P1.17.26 Evaluation of Large Language Models for Clinical Decision Support in Lung Cancer Treatment: ChatGPT-4.5 Vs. Deepresearch Vs. AvoMD

J. Lyu[1], S.M. Yoon[2], T.A. Djunadi[3], A. Tayyab[2], S. Maramreddy[3], J. Kim[4], R.S. Min[5], J. Park[6], Y.K. Chae[4]
[1]Cha University School of Medicine, Seongnam/KR ,[2]Jacobi Medical Center/North Central Bronx, New York/NY/USA ,[3]Richmond University Medical Center, Staten Island/NY/USA ,[4]Northwestern University Feinberg School of Medicine, Chicago/IL/USA ,[5]Northwestern University, Chicago/IL/USA ,[6]Chobanian & Avedisian School of Medicine, Boston/MA/US

Introduction: Artificial intelligence (AI) can reduce the documentation burden in oncology by supporting diagnostics and clinical decision-making through electronic health record (EHR) data analysis. Among large language models (LLMs), ChatGPT-4.5 is widely adopted and recognized for high accuracy and versatility. DeepResearch, a new agentic LLM powered by the O3 reasoning model, aims to generate evidence-based academically rigorous responses. Treatment guidelines in oncology are typically based on expert consensus and evidence, raising questions about whether AI models like DeepResearch could effectively complement or replace traditional guidelines in clinical decision-making. This study compares ChatGPT-4.5, DeepResearch, and AvoMD using real-world lung cancer patient data, evaluating each model's strengths and limitations in evidence-based clinical decision support.

Methods: Electronic health record (EHR) data—including clinical notes, imaging, laboratory, and pathology results—were collected from 13 lung cancer patients at Northwestern Hospital. Three LLMs (ChatGPT-4.5, DeepResearch, and AvoMD) were evaluated based on their ability to recommend treatments given the prompt: "What is the recommended treatment for this patient?" Only AvoMD was pre-loaded with NCCN Guidelines for Non-Small Cell Lung Cancer, Version 3.2025. Outputs were assessed using two metrics: Accuracy (1 = correct, 2 = mixed, 3 = incorrect) based on NCCN, ASCO, and ESMO guidelines, and Clinical Usefulness (1 = usable without modification, 2 = usable with modification, 3 = unusable in clinic).

Results: Across patient data summarization, AvoMD performed best, achieving 76.9% correct responses, surpassing DeepResearch and ChatGPT-4.5 (each 61.5%). For accuracy of treatment recommendations, DeepResearch was in the lead (69.2%), followed by AvoMD (61.5%) and ChatGPT-4.5 (53.8%). However, incorrect recommendations (Grade 3) were most frequent in DeepResearch and ChatGPT-4.5 (23.1% each), compared to AvoMD (7.7%). In clinical usefulness, AvoMD again ranked highest with 46.2% Grade 1 (usable without modification), followed by DeepResearch (38.5%) and ChatGPT-4.5 (30.8%). Most responses required some clinical modification (Grade 2), while ChatGPT-4.5 had the highest rate of clinically unusable outputs (23.1%). Qualitative analysis highlighted DeepResearch's strengths in referencing guidelines and generating evidence-based content but also revealed challenges with accurate cancer staging and patient-specific recommendations. ChatGPT-4.5 provided broad and flexible recommendations but occasionally generated clinically inappropriate content or misprioritized treatment options. AvoMD consistently adhered to guidelines with structured reasoning but sometimes overlooked patient-specific contexts such as comorbidities or palliative goals.

Conclusions: Large language models (LLMs) hold significant potential for supporting oncologists, particularly in summarizing complex clinical information and providing guideline-informed treatment recommendations. While DeepResearch demonstrated the strongest performance in generating evidence-based recommendations, its practicality is limited by lengthy computation times—often exceeding 15 minutes. In real-world clinical settings, time and resource constraints are critical factors. In our study, LLM reasoning agents pre-configured with NCCN guidelines proved more effective than those relying on real-time external searches. AvoMD, for instance, operates more like a real-time query engine focused on trusted clinical guidelines, rather than retrieving individual research articles. In conclusion, leveraging a single, expert-curated source like the NCCN guidelines minimizes variability and enhances consistency in AI-assisted clinical decision-making.

P1.17.27 Assessing Sarcopenia in Lung Cancer: Feasibility and Training Considerations of Using Quantitative Imaging Metrics From CT Scans

C. Adhikarla[1], C. Vega[1], F. Pezeshkian[1], A. Singh[2], P.F. Ugalde[1], L.N. Frain[1], M.T. Jaklitsch[1], D. Steimer[1], R.R. Gill[3]
[1]Brigham and Women's Hospital, Harvard University, Boston/MA/USA ,[2]University of Massachusetts, Chan Medical School, Worcester/MA/USA ,[3]New York Presbyterian Hospital, Columbia University, New York/NY/USA

Introduction: Sarcopenia, the loss of skeletal muscle mass and function, is an emerging prognostic factor in surgical resection of lung cancer. This study evaluates the feasibility of training thoracic surgeons to assess muscle mass on preoperative imaging.

Methods: Two thoracic surgeons were trained by a thoracic radiologist to review preoperative PET-CT/CT (Positron Emission Tomography-Computed Tomography) scans from patients who underwent lobectomy or segmentectomy. Muscle groups analyzed included pectoralis major, pectoralis minor, psoas, paraspinal, and total abdominal muscles bilaterally, at variable vertebral levels. For each muscle, maximum thickness, surface area, and average Hounsfield units (HU) were recorded. A root-cause analysis was conducted for the noted differences in measurements, and interobserver variability was assessed using Bland-Altman plots. A learning curve analysis was performed to track improvements in measurement efficiency.

Results: Twenty cases were randomly selected for this pilot cohort. Root-cause analysis indicated that knowledge of radiologic anatomy and a consensus on the vertebral level for measurement, significantly improved measurement accuracy and efficiency. The best four levels for measurements were middle of fourth thoracic vertebra for pectorals, twelfth thoracic vertebra at full emergence of ribs for paraspinals, and lower endplate of third lumbar vertebra for the psoas and total abdominal muscles. Surface area measurements showed significant improvement in agreement over time, whereas thickness measurements remained inconsistent. Pectoralis major and the psoas muscle related parameters achieved best consensus over time, while pectoralis minor had the most interobserver variability (Figure-1). Learning curves demonstrated progressive improvement, with the average time per scan stabilizing at 7.5 minutes (Figure-2).

Conclusions: This study suggests that non-radiologists can be trained to assess muscle mass measurements for sarcopenia using preoperative chest-CT/PET-CT scans, which are easily available and widely applicable, without requiring abdominal-CT and other three-dimensional reconstructions. Further research will explore correlations between these measurements and clinical outcomes to refine assessment methods.

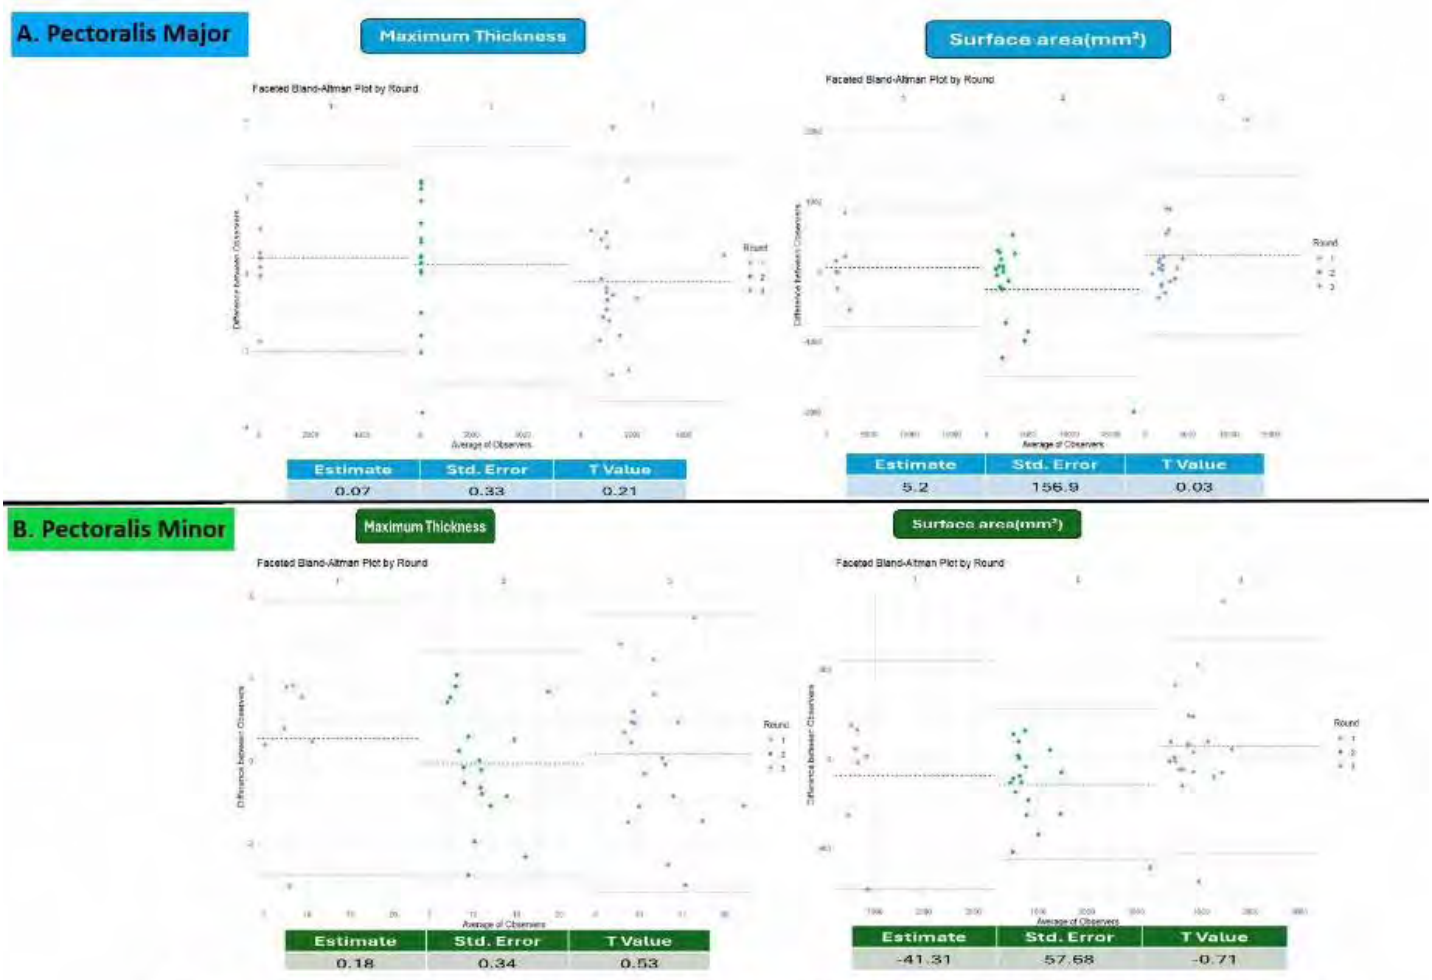

Figure-1: Trend in interobserver variability over time as noted in (A) Pectoralis Major versus (B) Pectoralis Minor

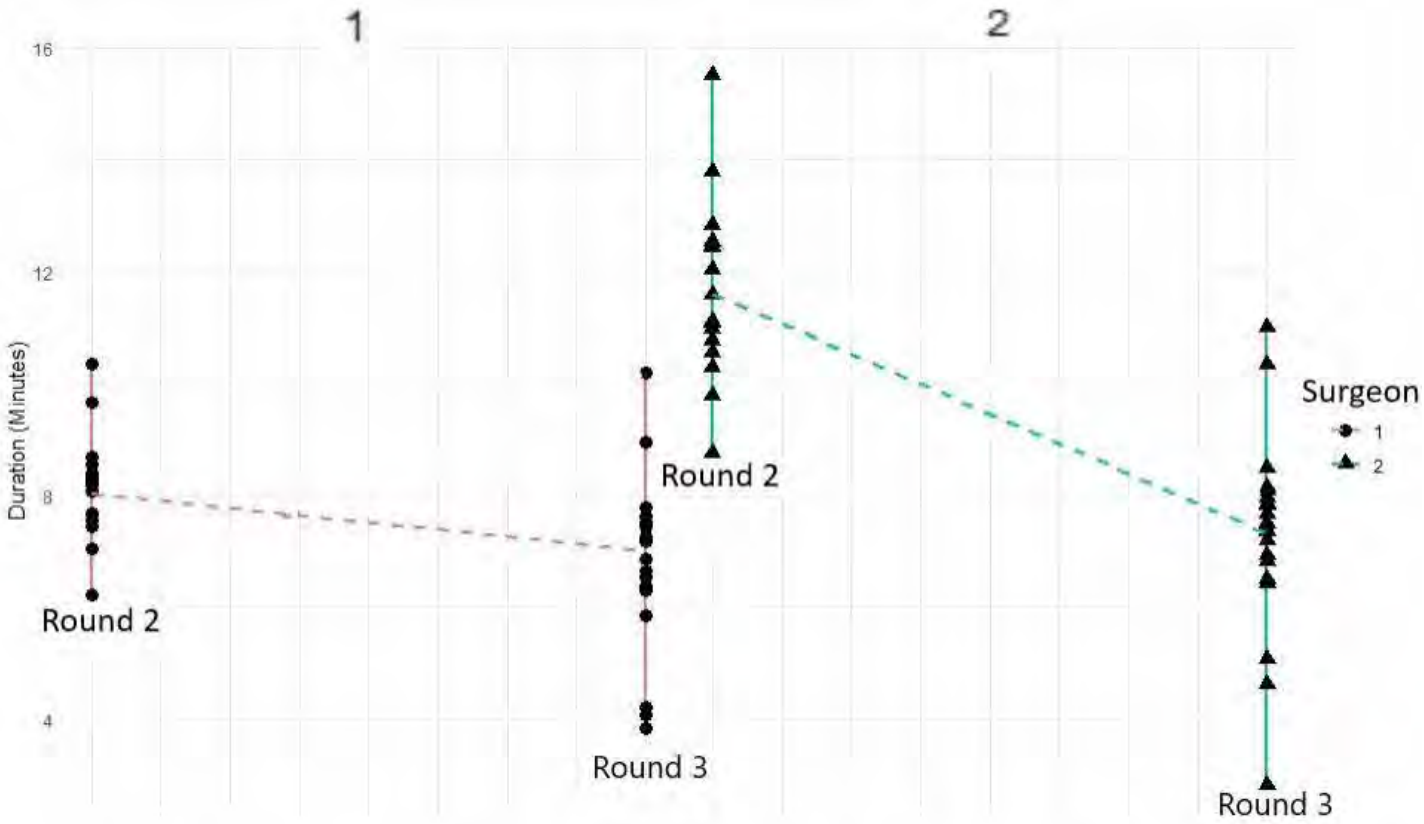

Figure 2: A comparison of learning curves of thoracic surgeons (1 vs. 2) trained in muscle mass measurements.

P1.17.28 Developing a Multifaceted Implementation Strategy to Increase Clinical Trial Accruals in Thoracic Oncology

A. Resnick, S. Lehman, K. Dick, D. Weinmann, J. Lensing, E. Sundsvold, A. Walston, J. Helgeson, T. Bleeker, J. Burton, J. Molina, A.S. Mansfield, A. Dimou, K. Parikh, M. Shanshal, K.E.R. Smith, A. Schwecke, A. Luce, A. Jasik, K. Leventakos
Mayo Clinic, Rochester/MN/USA

Introduction: Clinical trials are essential for advancing medical research and are a key priority at Mayo Clinic Comprehensive Cancer Center, yet enrollment of patients is suboptimal nationally. Barriers include a work culture that often prioritizes standard treatments, challenges in communicating risks and benefits, time-intensive accrual processes, and difficulties in trial matching. While tools such as trial matching systems, digital databases, and reporting tools are available, they have not been fully integrated to address these barriers effectively.

Methods: An integrated, system-driven process to develop solutions to barriers was completed including 1-1 feedback sessions with all physician and advance practice providers, observations, and a 7-question provider survey. The survey was completed at baseline and three-months post-intervention. A revised clinical trial accrual process was developed alongside frontline staff with frequent input from the provider team, designed to create closed-loop communication and leverage digital tools. Data was tracked on the number of clinical trial accruals pre- and post-intervention. The intervention was launched in Q4 2023, with the number of accruals tracked for the 12-month post-intervention in comparison with the prior period.

Results: Micro-interventions were implemented that correlated with an increase in clinical trial accruals and provider satisfaction, including (1) Trial summary sheets to synthesize trial information (2) A portfolio of active trials for the team on a digital screen (3) Workflow to integrate research nurses into the clinical practice. In the twelve months after the implementation, there was a 109% increase in accrual of patients to interventional thoracic oncology clinical trials. Before the implementation, 20% of providers felt they had enough support to easily enroll patients onto clinical trials, after implementation 80% of providers agreed with this statement (n = 5).

Conclusions: This project demonstrates that a systematic approach to identifying and addressing barriers to clinical trial participation can increase clinical trial accruals. Micro-interventions, such as integrating a research nurse, implementing trial summary sheets, and displaying active trial listings, optimized trial logistics, increased accruals and translated . Effective change management, including listening sessions and feedback, was pivotal in gaining stakeholder engagement and process buy-in. These strategies offer a scalable framework for other cancer care teams to enhance clinical trial participation and advance medical research.

Introduction: Swift advancement in anticancer drug development in the last two decades for the treatment of NSCLC (non-small cell lung cancer) patients poses challenges in availability of these therapies in European Union (EU) member states (MS). Although EU MS share the same regulatory status, access to anticancer treatments vary significantly.

Methods: Using a questionnaire sent to experts in EU MS, we analysed the availability and accessibility of NSCLC anticancer therapies incorporated in the European Society for Medical Oncology (ESMO) guidelines and graded by the ESMO MCBS (Magnitude of Clinical Benefit Scale) committee. The reimbursement status was retrieved for 18 EU MS: Austria, Bulgaria, Croatia, Cyprus, Estonia, Germany, Greece, Ireland, Italy, Lithuania, Luxembourg, Netherlands, Poland, Portugal, Slovakia, Slovenia, Spain, and Sweden. Reimbursement categories included fully reimbursed (paid by insurance in full), partially reimbursed (patients cover some expenses), per patient reimbursement (based on individual application, then covered in full), out-of-pocket (patients cover all expenses), compassionate use program or donation (available through various programs), clinical trial (any phase for that indication), and unavailable. Data cut-off: 01-Jan-2025.

Results: Thirty-three anticancer therapies for 59 indications were found in the ESMO NSCLC guidelines, which were approved by the EMA (European Medicines Agency) and another three without indication at data cut-off. Of them, 27 received a high ESMO MCBS score (4 or 5) and another six with score A, which indicate substantial clinical benefit. Overall, 3 therapies are fully reimbursed in all MS, and additional 8 are not fully covered in only one MS. Moreover, three MS have more than 90% of identified therapies fully reimbursed, while the median number of fully reimbursed therapies are 63%. On the other hand, one MS has less than 25% of therapies fully reimbursed; however, this MS covers 71% of therapies through per patient reimbursement scheme. In general, small number of indications are available for out-of-pocket payments, except in two MS with 56% and 68% of such payments, respectively. Another two MS have high number of unavailable treatments, 61% and 48%, respectively. A median number of fully reimbursed targeted therapies for either EGFR, ALK/ROS1 and all other molecularly positive patients across MS are 9, 14, and 6, respectively. Eighty percent of EGFR and 50% of ALK/ROS1 inhibitor indications with ESMO MCBS score of 4 are at least partially covered in every MS. More than half of the immune checkpoint inhibitors either as mono- or combination treatment with MCBS score of 4, 5 or A are fully reimbursed in almost all (16) MS. Similarly, at least three out of six treatment indications for early NSCLC with ESMO MCBS score A are available free of charge in 16 MS.

Conclusions: Although EU MS operate under a shared regulatory framework, reimbursement systems differ, yet still generally provide access to most clinically meaningful anticancer therapies for NSCLC patients. However, disparities are still evident and need to be adressed in the future to improve anticancer therapies availibilty.

Keywords: Access to anticancer therapies, EU member states, Non-small cell lung cancer

[1]Politecnico di Milano, Milan/IT ,[2]Fondazione IRCCS Istituto Nazionale dei Tumori, Milan/IT ,[3]Policlinico Universitario Fondazione "A.Gemelli" IRCCS, chiara.bonalume@istitutotumori.mi.it/IT ,[4]University of Chicago Medical Center, Chicago/IL/USA

Introduction: Accurate prediction of treatment outcomes in Non-Small Cell Lung Cancer (NSCLC) remains a major clinical challenge. AI-based models hold significant potential for identifying novel imaging-based biomarkers to enhance treatment efficacy prediction. In this context, accurate gross tumor volume (GTV) segmentation is crucial for response assessment. However, manual segmentation is time-consuming and expert-dependent. Deep Learning provides a promising approach for automatic segmentation. This study evaluates the performance of nnU-Net automatic segmentation method in supporting AI-driven survival analysis using baseline CT scans. The objective was to compare expert-provided and automated segmentation methods, assessing their impact on survival models.

Methods: We used three NSCLC datasets composed of baseline lung CT scans with expert-delineated GTVs. We included two public datasets: 402 CT scans from NSCLC-Radiomics TCIA dataset and 63 from Medical Segmentation Decathlon (MSD). Additionally, we used an in-house dataset (NCT0550961) of 276 scans of NSCLC patients treated with immunotherapy at Fondazione IRCCS Istituto Nazionale dei Tumori (INT). To allocate different patients for training automatic and survival analyses, we used 63 MSD CTs and 126 TCIA scans exclusively for training automatic segmentation. Two sets, consisting of the remaining 276 TCIA and 276 INT scans, were reserved for testing automatic segmentation and conducting survival analysis. We evaluated both nnU-Net and state-of-the-art Primakov method for automatic segmentation, assessing performance using Dice similarity coefficient. We extracted 107 radiomic features from nnU-Net, Primakov, and expert-provided GTVs using PyRadiomics. We performed feature selection by combining univariate Cox regression with correlation analysis (threshold=0.75). Four Machine Learning (ML) survival models were trained to predict Overall Survival using features derived from each segmentation method. We assessed models' performance using 10-fold cross-validation based on concordance index (C-index) and we used Friedman test to assess statistically significant differences in performance.

Results: The nnU-Net segmentation method outperformed the Primakov method in terms of Dice score. Figure 1 shows the C-index of survival predictions of the three analyzed methods, using the best-performing ML model for each. The Friedman test confirmed that the performance differences were not statistically significant, with all p-values > 0.05.

Conclusions: In this study, automatic segmentation methods demonstrated comparable performance to those performed by radiologists in survival models. While further validation on larger cohorts is needed to ensure generalizability, these findings highlight the potential of emerging technologies to automate the segmentation process, reducing human effort without compromising performance. In some cases, limited data manipulation may support more data-driven and unbiased image analysis.

P1.17.31 Feasibility of Integrating Ai-Assisted Lung Cancer Screening in High Tuberculosis Burden Settings

V.M. Balanag[1], I.V. Elepano[2], A.J. Codlin[3], T.P. Dao[3], A.B. Binegdie[4]
[1]Lung Center of the Philippines, Quezon City/PH ,[2]Asian Hospital and Medical Center, Manila/PH ,[3]Friends for International TB Relief (FIT), Ho Chi Minh City/VN ,[4]Addis Ababa University, Addis Ababa/ET

Introduction: Lung cancer (LC) and tuberculosis (TB) share overlapping clinical and radiological features, often leading to misdiagnosis and delayed treatment. TB screening programs in low- and middle-income countries are increasingly using artificial intelligence (AI) to interpret chest X-ray (CXR) images for TB detection. This presents an opportunity for additional LC screening, which often goes undiagnosed and untreated, with minimal incremental resources. This project's aim was to observe the application of the AI software, qXR for lung cancer screening in high TB burden settings.

Methods: Community- and facility-based CXR screening for TB was conducted in Ethiopia, the Philippines, and Vietnam. CXR images from these programs/centers were processed using qXR AI software (Qure.ai, India) and those with potentially malignant lung nodules were referred for a CT scan as part of a lung cancer screening feasibility pilot. CT scans were analysed by a radiologist using the Lung RADS scoring system and post-CT scan care followed local clinical guidelines.

Results: A total of 198,271 CXRs screened for TB were also analyzed for the presence of lung nodules using AI as part of the feasibility pilot across the three countries. 3,518 (1.8%) potentially malignant lung nodules were detected by the qXR AI software, from which further information was available for 2,232 (63.4%). A total of 725 (32.5%) CT scans were performed, resulting in the detection of 497 (68.6%) with a Lung RADS score ≥4A.

Conclusions: These pilot findings show that integrating AI-assisted CT referrals for LC screening into CXR screening programs for TB is feasible approach for scaling up LC screening. Further studies assessing how AI-assisted LC screening can improve population-level LC treatment and patient outcomes, as well as the cost-effectiveness of this approach, are warranted.

P1.17.32 Comparing ChatGPT's and Google Gemini'S Responses to Lung Cancer Questions

C. Kim[1,2], P.K. Chaturvedi[2], J.Y. Kim[2], S.E. Park[1,2], J. Lee[3], H.J. Min[4], C-H. Seong[4], S.H. Nam[5], D. Kim[2,5]
[1]Chungbuk National University, Cheongju/KR ,[2]DK Lab, Chungbuk National University and Hospital, Cheongju/KR ,[3]Deepnoid Inc, Seoul/KR ,[4]Chungbuk National University College of Medicine and Hospital, Cheongju/KR ,[5]Chungbuk National University and Chungbuk National University Hospital, Cheongju/KR

Introduction: People who are not experts in lung cancer often struggle to keep up with advances in the field. While ChatGPT and Gemini have the potential to provide quick and accessible medical information, their suitability and reliability remain unverified. We evaluated the appropriateness of these AI models for providing lung cancer information.

Methods: We selected 40 questions from the Korean Association for Lung Cancer, categorized them into five domains, and then presented these questions to ChatGPT and Gemini. The AIs generated 80 answers and cited 262 references. Twenty medical professionals including physicians (n=10) and nurses (n=10) assessed accuracy, relevance, and sufficiency using a 5-point Likert scale, while ten patients evaluated understandability using the same scale. Readability was assessed using the Flesch Reading Ease (FRE) and Flesch-Kincaid Grade Level scores. Additionally, references were analyzed for consistency, evidence level, region, and type.

Results: ChatGPT provided more consistent references than Gemini (Consistency: 91.16% vs. 48.79%, $P < 0.0001$), whereas Gemini generated more readable answers (FRE: 29.81 vs. 42.91, $P < 0.0001$). The proportion of references from Korean sources was lower in ChatGPT than in Gemini (ChatGPT: 10.88% vs. Gemini: 79.13%, $P < 0.0001$). While there was no significant difference in accuracy (Physician, $P = 0.9451$) (Nurse, $P = 0.5438$), relevance (Physician, $P = 0.9757$) (Nurse, $P = 1.0000$), understandability (Patient, $P = 0.9292$), evidence level ($P = 0.8488$), and type ($P = 0.9532$), Gemini exhibited hallucination effects in references (Hallucination, n = 7). In contrast, ChatGPT demonstrated a more reliable citation process (Hallucination, n = 0).

Conclusions: ChatGPT provided more reliable references than Gemini in answering lung cancer questions. Although ChatGPT's and Gemini's answers were comparable, ChatGPT appears more suitable for providing lung cancer information to people who are not experts in the field.

P1.17.33 Addressing Educational Gaps in Lung Cancer Care: Insights Based on Global Practice Setting and Experience

M.A. Worst[1], N. Dorkham[1], Z. Fiske[1], J. Schwartz[1], S. Patel[2], M. Perol[3]
[1]Medscape LLC, Newark/NJ/USA ,[2]University of California San Diego, San Diego/CA/USA ,[3]Léon Bérard Cancer Center, Lyon/FR

Introduction: Practice setting and years of experience play critical roles in shaping oncologists' (oncs) approach to lung cancer care, especially given its rapidly evolving landscape. The objective was to assess how practice setting and years in practice influence oncs' understanding of key management concepts in lung cancer.

Methods: The analysis included 63 online, continuing medical education (CME)-certified activities. Educational impact was measured with pre-/post-education assessments including multiple-choice knowledge/competency questions and 5-point Likert scale confidence questions. Data from onc learners who completed pre- and/or post assessments were aggregated across activities and stratified by practice setting, experience, and learning themes. Relative changes in percentage of correct responses and level of confidence (value of 4 or 5) were used to measure impact, with significance measured via McNemar tests ($P < .05$). Data collected through March 2025.

Results: Statistically significant improvements ($P < .01$) were observed across learning themes, regardless of practice setting or years in practice. Outside the United States (OUS) oncs demonstrated higher relative changes compared to United States (US) oncs across all themes, with the exception of awareness of disparities and challenges in care. Confidence staying abreast of and applying evolving data remained one of the largest gaps across all groups (≥70%). Overall relative changes presented below (N=48 to 2252).

Conclusions: Findings suggest that recent education had a more pronounced impact on OUS oncs' understanding of lung cancer management, regardless of practice setting, suggesting a higher baseline need for education. US oncs' had a generally stronger baseline knowledge and confidence, but showed smaller relative improvements, indicating a need for more advanced or targeted education. Despite progress, persistent challenges remain, highlighting critical focus areas for future initiatives. The true effect of these activities on corresponding clinical practices requires further study.

Learning Theme	OUS Oncologist % Change		US Oncologist % Change	
	≤5 Years in Practice	>5 Years in Practice	≤5 Years in Practice	>5 Years in Practice
Ability completing comprehensive work-up	146	121	27	35
Awareness of disparities and/or challenges in care	8	8	10	13
Competence tailoring treatment decisions	97	123	10	30
Confidence communicating and collaborating with the MDT	131	128	16	33
Confidence prioritizing patient values and preferences in care	129	55	43	16
Confidence staying abreast of and applying evolving data to clinical practice	67	42	14	39
Knowledge of biomarkers	76	69	47	42
Understanding of clinical trial data	93	100	59	58

P1.17.34 Assessing the Outcome of 10-Year Lung Cancer Survivors and the Necessity of Long-Term Postoperative Surveillance

S. Shiono[1], J. Suzuki[1], H. Watanabe[1], S. Takamori[1], M. Endo[2]
[1]Yamagata University, Yamagata/JP ,[2]Yamagata Prefectural Central Hospital, Yamagata/JP

Introduction: Recurrence and second primary lung cancer may occur at 10 years after lung cancer surgery. However, few studies exist of lung cancer survivors at 10 years or more after surgery. In addition, the necessity and standard schedule of long-term postoperative surveillance has not been clarified. There is no consensus regarding the appropriate postoperative surveillance period. Here, we assessed the prognosis of 10-year lung cancer survivors who underwent lung cancer surgery.

Methods: Between May 2004 and December 2014, 1,154 patients underwent complete resection of lung cancer. After excluding patients who died after less than 10 years, who missed follow-up, or whose outcomes were unknown, 449 (39.0%) patients surviving 10 years after surgery were assessed.

Results: The median follow-up time and median age at surgery were 11.8 and 67 years, respectively. Median survival time after 10 years was 7.6 years. Two hundred ninety (64.6%) and 159 (35.4%) patients had stage 0-IA and stage IB-III disease, respectively. Forty-six (10.2%) patients had cancer recurrence at 10 years after surgery. Three (0.7%) patients developed recurrence and 11 (2.5%) patients developed second primary lung cancers 10 years after surgery. The 15-year overall survival rate was 68.3% (Figure). Univariable analyses revealed that age (≥70 years) ($p < 0.001$), male ($p < 0.001$), smoking ($p < 0.001$), carcinoembryonic antigen (>5 ng/ml) ($p = 0.007$), forced expiratory volume in the first second / forced vital capacity % (<70%) ($p = 0.002$), standardized max value (≥3.0) on positron emission tomography/computed tomography ($p = 0.020$), non-adenocarcinoma ($p = 0.001$), tumor size (>3cm) ($p = 0.020$), invasive focus size ($p = 0.021$), and histological grade 2 or 3 ($p = 0.017$) were prognostic factors. Multivariable analysis confirmed that age (≥70 years) ($p < 0.001$) was the only prognostic factor for 10-year lung cancer survival. Receiver operating curve analysis showed that 64 years was a cut-off value for better prognosis.

Conclusions: Age was the prognostic factor for 10-year lung cancer survival. Given that recurrence is very rare, and cancer-related factors were not prognostic factors in multivariable analysis, the prognosis of 10-year lung cancer survivors is promising and postoperative surveillance after 10 years may not be necessary. However, as there is a potential risk of second primary lung cancer, 10-years-or-more lung cancer survivors would need annual health check-ups.

P1.17.35 Patient Navigation and the Opportunity to Improve Experiences and Outcomes of Lung Cancer Care

J. Hooper, H. Wilcox, E. Wheeler
The Health Policy Partnership, London/GB

Introduction: The Lung Cancer Policy Network is a global network of multidisciplinary experts from the lung cancer and oncology community. This year, the Network has developed a comprehensive report that makes the case for patient navigation as an essential component of lung cancer care and provides recommendations for its integration throughout the care pathway. The comprehensive and coordinated service delivery promised by patient navigation programmes could alleviate the strain on the world's health systems caused by lung cancer - the leading cause of cancer-related deaths. By guiding people through the health system, patient navigators can address barriers to timely care along the care pathway, decrease the impact of fragmented services, and promote holistic, person-centred care. For a variety of cancer types, there is compelling evidence supporting the role of patient navigators in treatment and care. But studies on patient navigation specifically for lung cancer are few, and there are limited strategies for implementation; patient navigator initiatives originated in the US and have only recently started to emerge in Europe, with varying levels of application.

Methods: The report was informed by a review of existing peer-reviewed and grey literature, interviews with 14 experts (including programme coordinators, clinicians, navigators, implementation researchers, patients and advocates) and insights from members of the Lung Cancer Policy Network. The report also incorporates practical case studies and examples from around the world.

Results: This report identifies tangible actions for implementing and optimising patient navigation for lung cancer; the recommendations have been developed to be adaptable depending on the needs of different health systems and countries/regions, and recognise that approaches to lung cancer care are evolving. Recommended actions include: to address barriers to sustainable funding and governance; to create patient navigation models and frameworks that can be flexible to individual needs; to accelerate research into the potential benefits of new technologies and dedicated digital navigator roles; and to engage communities and the health system in the development of tailored patient navigation programmes and training.

Conclusions: To our knowledge, this report presents the first series of recommendations to support the implementation of patient navigation programmes for lung cancer. Lung cancer care is multidisciplinary and complex, and there are many barriers to delivering equitable care. Effective patient navigation helps deliver a holistic and high-quality experience for all people with lung cancer, driving improvements in outcomes and optimising the use of infrastructure and resources. This in turn may help address inequities that persist along the lung cancer care pathway, with differences in incidence, mortality and outcomes observed for a variety of factors, including sex, age, race, ethnicity and socioeconomic status. To realise this opportunity to reduce inequalities in lung cancer care, health system leaders and decision-makers must assess and identify how patient navigation can improve current practice, develop navigation programmes where they do not exist, and optimise these programmes accordingly.

Introduction: The project aimed to explore the knowledge, perspectives, and practice regarding health-related quality of life (HRQoL) and patient-reported outcome measures (PROMs) among physicians and patients with ALK-positive NSCLC in China, focusing on similarities and differences in their perception and expectations.

Methods: This cross-sectional online survey, conducted from September to October 2024, included a representative sample of 200 physicians and 200 patients in China. Physicians experienced in treating ALK-positive NSCLC in tertiary or secondary hospitals and adult patients who received ALK-TKIs for first-line treatment were included. Descriptive statistics were used for data analysis.

Results: Respondents included physicians (median age: 45 years, 61.5% male) and patients (median age: 58 years, 44.0% male, median disease duration: 3 years). The majority of physicians (65.5%) and patients (60.0%) were familiar with HRQoL (rated as extremely or very, the same below). Most respondents acknowledged the importance of each HRQoL functional dimension in managing ALK-positive NSCLC (Figure A). Patients valued the impact of ALK-TKIs on HRQoL more than physicians, who prioritized efficacy, safety, and drug accessibility (Figure B). Regarding symptoms (Figure C), physicians considered coughing, hemoptysis, and shortness of breath as the top 3 symptoms influencing HRQoL, whereas patients identified cancer pain, peripheral neuropathy, and loss of appetite as most impactful. Moreover, 17.5% of patients regarded cognitive impairment and hallucinations as affecting their HRQoL, compared to 9.0% and 1.5% of physicians, respectively. Awareness varied among respondents who had heard of HRQoL PROMs: 69.1% (123/178) of physicians and 44.1% (45/102) of patients were familiar with them. Differences were also observed in HRQoL clinical practice: 76.0% of physicians spent <40% of their time discussing HRQoL with patients, while 45.0% of patients expected physicians to dedicate ≥40% of the consultation to this topic. About two-thirds of physicians (67.0%) reported using HRQoL PROMs, while less than one-third of patients (32.5%) did for disease management. Despite these differences, both groups expressed a desire of more HRQoL knowledge: 83.0% of physicians anticipated training on HRQoL PROMs application or easier results interpretation, while 78.5% of patients desired more HRQoL knowledge dissemination.

Conclusions: This national survey underscores a substantial awareness of HRQoL among physicians and patients with ALK-positive NSCLC, but discrepancies in awareness and use of HRQoL PROMs persist. Differences in perceptions of HRQoL discussions and PROMs application highlight the need for better integration into clinical practice. Targeted education and training may help harmonize understanding and enhance patient-centered care in the management of ALK-positive NSCLC.

Figure. A) Perception of importance on various dimensions of HRQoL by physicians and patients. B) Perception of importance on various dimensions related to ALK-TKIs by physicians and patients. C) Perception of influence of various symptoms on HRQoL by physicians and patients.
Abbreviations: HRQoL: Health-related quality of life; ALK-TKI: Anaplastic lymphoma kinase tyrosine kinase inhibitor; NSCLC: Non-small cell lung cancer
Note: Options selected by 0 respondent are not displayed with numbers in the figure.

P1.17.37 Providing Equal Access to Lung Cancer MDT Consultation Through Digital Innovation

X. Cheng[1], Z. Li[1], X. Cai[1], H. Zhang[1], P. Cui[2], B. Yin[2], J. Cai[3], C. Mao[3], S. Zhang[3], M.T. Campos[4], H. Naqvi[5]
[1]Shanghai Lung Cancer Center, Shanghai Chest Hospital, Shanghai JiaoTong University School of Medicine, Shanghai/CN ,[2]VINTURA, Baarn/NL ,[3]Astrazeneca, Shanghai/CN ,[4]Astrazeneca, Barcelona/ES ,[5]Astrazeneca, Gaithersburg/MD/USA

Introduction: Cancer treatments vary due to care inequality across regions, and socioeconomic groups. In China, lung cancer has high mortality of 733K deaths annually, accounting for 40.3% of world total. Lower-tier hospitals, mainly in county-level areas, face challenges in lung cancer care due to limited resources and expertise. Inter-hospital remote multidisciplinary team (iMDT) consultations offer a promising approach to sharing medical resources and improving lung cancer diagnosis and treatment. An AI-based digital platform has been developed to facilitate this. This study aims to share best practices of the iMDT digital platform, evaluate its effectiveness, and extract replicable experiences for other MDT teams.

Methods: Focus groups of HCPs and tech experts determined key data inputs and outputs for the iMDT digital platform. This platform was used in 20 remote MDT sessions between lower-tier hospitals and Shanghai Chest Hospital to discuss 70 patient cases. Relevant data from MDT management were automatically generated and recorded. Semi-structured qualitative feedback surveys were collected from over 30 HCPs, along with their feedback on patient post-MDT performance for analysis.

Results: The iMDT digital platform systematically extracted and structured four key categories of patient information:

1. Anonymized demographic data (age and gender).
2. Pre-MDT diagnosis details and clinical staging from lower-tier hospitals.
3. Pre-MDT treatment history, including surgery, systemic therapy, and radiation therapy.
4. Final MDT diagnosis and treatment plan, signed off by the MDT chair.

The platform demonstrated five core benefits:

1. Enhanced efficiency in MDT preparation and case discussions.
2. Standardized review and auditing to assess guideline concordance.
3. Creation of a patient case library for physician training and education.
4. Establishment of a structured database for patient follow-up and monitoring.
5. Foundation for predictive analytics, enabling future patient outcome forecasting.

User feedback revealed a high satisfaction rate, with over 95% of HCPs advocating for its wider adoption, citing improvements in workflow efficiency and diagnostic accuracy. Additionally, more than 90% of patients expressed confidence in MDT decisions, suggesting a positive impact on shared decision-making and patient-centered care.

Conclusions: The iMDT digital platform facilitates more structured, efficient, and standardized MDT discussions, addressing regional disparities in lung cancer care, particularly in underdeveloped areas. By integrating AI-driven data extraction and decision support, the platform enhances diagnostic precision, treatment planning, and physician education. The observed high levels of HCP and patient satisfaction highlight its clinical utility and scalability. Future enhancements, including expanded data collection and AI-driven predictive modeling, could further personalize MDT recommendations and refine treatment strategies, ultimately improving patient outcomes.

P1.17.38 A Two-Layer MDT Model as the Standard of Care for Lung Cancer - a Good MDT Example With High-Volume Patients in Central Western China

Z. He[1], Y. Liu[1], G. Liang[1], L. Wang[1], D. Zhao[1], S. Yang[1], S. Ma[1], Y. Wu[1], H. Chen[1], P. Cui[2], J. Cai[3], C. Mao[3], M.T. Campos[4], H. Naqvi[5], Q. Wang[1]
[1]The Affiliated Cancer Hospital of Zhengzhou University & Henan Cancer Hospital, Institute of Cancer Research, Henan Academy of Innovations in Medical Science, Zhengzhou/CN ,[2]VINTURA, Baarn/NL ,[3]Astrazeneca, Shanghai/CN ,[4]Astrazeneca, Barcelona/ES ,[5]Astrazeneca, Gaithersburg/MD/USA

Introduction: China reported 820,000 new lung cancer cases in 2020, representing 37% of global cases. Central-Western China is home to over 700 million people—comparable to Europe's population. Managing lung cancer in this vast, resource-limited region is a major public health challenge. As diagnosis and treatment involve multiple specialties, a well-structured MDT ensures accurate diagnosis, treatment coordination, and timely care. This study evaluates a model of Henan Cancer Hospital — one of Chinese biggest cancer centers with 3,000 beds and designated Lung Cancer Center for Henan province (population ~100 million). The hospital treats over 6,000 new lung cancer cases annually and has more than six years of MDT experience, providing a valuable best-practice case for high-volume MDT implementation in high-burden regions.

Methods: We conducted 10+ expert interviews and 2 workshops with MDT members across 10+ specialties from Henan Cancer Hospital, including thoracic surgery, medical oncology, radiology, pathology, and radiation oncology to gain insights around their specific two-layer lung cancer MDT implementation.

Results: Henan Cancer Hospital developed a two-layer MDT model (see Table 1) to efficiently manage high patient volumes by triaging cases based on disease stage and complexity. 1). The first layer—MDT Clinic focuses on early-stage pulmonary nodules, reducing unnecessary surgeries through multi-specialty input. 2). The second layer—Inpatient Lung Cancer MDT covers all newly diagnosed lung cancer cases, ensuring timely, standardized decisions. This model achieved improved resource allocation by reducing unnecessary surgeries (20-30%), shortening hospital stays, and increasing discharge rates. Optimized resource reduced the hospital's average treatment cost for lung cancer by over 50% compared to other provincial hospitals, demonstrating significant economic benefits. Through the MDT, every patient receives a standardized diagnosis and treatment plan aligned with clinical guidelines. Given the hospital's high patient volume, these benefits scale effectively, amplifying cost savings, efficiency gains, and improved treatment outcomes. Beyond hospital-level improvements, Henan Cancer Hospital extends its expertise through regular remote MDTs via the 'iMDT' platform, enabling lower-tier hospitals to manage more cases locally. This approach reduces unnecessary referrals and healthcare costs while enhancing regional medical resource allocation.

Conclusions: Henan Cancer Hospital's two-layer MDT model provides a scalable and effective framework for delivering high-quality, cost-effective lung cancer care in high-volume settings. Additionally, through remote MDTs, it enables lower-tier hospitals to improve MDT capacity. This approach could serve as a replicable best practice for hospitals in China and worldwide facing similar challenges, ultimately improving patient outcomes and increasing cost-effectiveness in public healthcare systems.

Table 1. Key Characteristics of the Two-Layer MDT Model

MDT type	First layer—MDT Clinic	Second layer—Inpatient Lung Cancer MDT
Scope	Early-stage pulmonary nodules	All newly diagnosed lung cancer cases
Specialties	Led by thoracic surgeons, with support from respiratory medicine, radiation oncology, interventional radiology, and imaging specialists	Rotating leadership among multiple departments
Frequency	Weekly	4 times/week
Volume	15 cases/session, 5-20 min/ case	~6,000 cases/year, 1-6 min/ case
Patient Involvement	Patients and families participate in discussions	Patients directly receive results the same day
Key Outcomes	- 20-30% reduction in unnecessary surgeries - Minimizes overtreatment - Enhances psychological support	- Improves staging accuracy - Strengthens medical education - Extends expertise via remote MDTs

P1.17.39 Clinical Predictive for Early Mortality in Stage IV Lung Cancer Without Targetable Mutations From Country With High Smoking Prevalence

A.M. Zayed[1], M. ma'koseh[1], A. Ahmad[1], M. Fraihat[2], S.A. Yousef[1], Y. Khater[1], S. Yaser[1], Y. Talab[1], A. Al-Ibraheem[1], R. Abdeljalil[1], L. Nemrawi[1], Q. Alnajjar[1], D. Dahbour[2], Y. Hamadneh[2], O. Younis[2], M. zayed[3], T. Al-Batsh[1], K. Al-Rabi[1]
[1]king hussein cancer center, Amman/JO ,[2]Jordan University, Amman/JO ,[3]Jordan University of Science and Technology JUST, Irbid/JON

Introduction: Lung cancer is the leading cause of cancer mortality worldwide; approximately 25%-30% of patients with stage IV non-small cell lung cancer (NSCLC) die within 3 months of diagnosis (early mortality). Identifying high-risk patients could influence treatment decisions and outcome. This study examines clinical characteristics and risk factors for early death.

Methods: Medical records of patients aged 18 years or older, initially diagnosed with stage IV NSCLC, tested for PD-L1 expression, and confirmed negative for EGFR, ALK, and ROS1 at King Hussein Cancer Center from 2017 to 2024 were retrospectively reviewed. They were divided into patients who died within 3 months of diagnosis (early mortality) and patients who died later. Clinical variables were compared using Pearson's chi-squared tests, likelihood ratio chi-square, Mann-Whitney U tests, and linear model ANOVA.

Results: A total of 721 patients were included; 243 (41.2%) died within 3 months of diagnosis; the majority were male (604, 83.8%); the median age was 60 years; adenocarcinoma was the most common subtype (525, 72.8%); and the performance status (PS) of 3-4 was reported in 128 patients (17.8%). The PD-L1 expression ≥50% was observed in 225 (31.2%). The most common comorbidities were hypertension (37%) and diabetes mellitus (30%), while hyponatremia was the most common electrolyte abnormality at diagnosis (161, 22.3%). Brain metastases were reported in 331 (45.9%) patients, and adrenal metastases in 207 (28.7%). A total of 280 patients (39%) received immunotherapy either as a single agent or in combination, while 162 (22.5%) did not receive any systemic therapy. The early mortality group was older, with a median age of 62 vs. 59 (P = 0.001), and it was associated with PD-L1 ≥50% (37% vs. 27.1%; OR = 1.6, 95% CI: 1.03-2.52, p = 0.037), ECOG PS 3-4 (34.6% vs. 10.7%; OR = 4.09, 95% CI: 2.61-6.50, p < 0.001), adrenal metastases (38.7% vs. 25.5%; OR = 1.79, 95% CI: 1.21-2.63, p = 0.003), and congestive heart failure (CHF) (5.3% vs. 1.7%; OR = 2.65, 95% CI: 0.97-7.96, p = 0.066). Palliative care consultation at the time of diagnosis was associated with less frequent deaths in the intensive care unit (39.9% vs. 72.5%, p < 0.001). Patients receiving palliative care were less likely to die from treatment side effects (5.4% vs. 10.9%) or co-morbidities (5.7% vs. 10.0%, p = 0.0051). However, it did not influence the site of death (home vs. hospital).

Conclusions: A substantial proportion of patients initially diagnosed with Stage IV NSCLC die early, before reaching their first disease assessment. Risk factors such as older age, high PD-L1 expression, poor ECOG PS, and adrenal metastases should guide treatment decisions and follow-ups. Early palliative care is essential, reducing ICU deaths, treatment-related mortality, and ensuring improved quality of life.

P1.17.40 Impact of Remote MDT Through a Digital Platform: Insights From 70 Patient Follow-Ups

X. Zhang[1], C. He[1], G. Liang[1], K. Ye[1], L. Kang[1], C. Shi[1], P. Cui[2], H. Wang[1]
[1]The Affiliated Cancer Hospital of Zhengzhou University/Henan Cancer Hospital, Zhengzhou/CN ,[2]VINTURA, Baarn/NL

Introduction: Multidisciplinary Team (MDT) management is essential for lung cancer diagnosis and treatment. However, disparities between urban and rural areas in China limit access to standardized MDT care. Remote MDTs, facilitated via digital platforms, help bridge this gap by providing lower-tier hospitals with expert guidance, standardized treatment, and multidisciplinary decision-making. This study evaluates a digital remote MDT model using physician-assessed patient outcomes to measure its impact on patient care and quality of life.

Methods: An AI-based digital MDT platform, "iMDT," enabled remote MDT sessions between lower-tier hospitals and Centers of Excellence (CoE). Following these sessions, healthcare providers (HCPs) at lower-tier hospitals conducted patient follow-ups every 2-3 months (3-4 follow-ups total) and completed structured questionnaires (see Table 1) assessing quality of life, treatment effectiveness, physical, psychological & conscious status, social reintegration, and overall MDT satisfaction. For treatment effectiveness, a combination of Response Evaluation Criteria in Solid Tumors (RECIST 1.1) and physician assessment was applied. By January 2025, data from 70 eligible patients across 40 lower-tier hospitals had been collected by treating physicians (including 55 responses for treatment effectiveness) and analyzed for insights.

Results: Among the 70 eligible patients, 71% reported an improvement in quality of life since their last follow-up, with 47% "significantly improved." In terms of treatment effectiveness, 43 patients were evaluated using RECIST 1.1 and 12 through HCP assessment. Among them, 51% showed a complete or partial response, while 13% remained stable, demonstrating the clinical efficacy of remote MDT interventions. Patient satisfaction levels were high across multiple dimensions, with 91% rating their MDT-based treatment plan as good or excellent. With regards to specific sub-dimensions, 84% reported good or excellent physical status, 80% reported good or excellent psychological status, and 92% reported good or excellent conscious status. Additionally, 83% stated that recovery allowed them to reintegrate into social life, highlighting both clinical and social benefits. These findings demonstrate that remote MDTs improve treatment decisions, patient experience, and multidisciplinary collaboration, reinforcing their value in expanding access to high-quality cancer care.

Conclusions: Remote MDTs via AI-based platforms improve patient outcomes, enhance treatment effectiveness, and ensure high satisfaction rates. The structured questionnaire provides a standardized method for evaluating MDT effectiveness, supporting continuous quality improvement in multidisciplinary cancer care. Expanding such standardized assessment processes will help optimize MDT models and enhance care delivery in lower-tier hospitals.

Table 1. Questionnaire of remote MDT follow up

Question	Answer Options
How would you assess the patient's overall quality of life?	Much improved / Somewhat improved / No significant change / Worse
Has the patient achieved an objective response according to ORR criteria?	Yes, through RECIST 1.1 / Yes, through physician's Assessment / No
What is the patient's RECIST 1.1 evaluation result?	Complete response / Partial response / Stable disease (Non-CR/Non-PD) / Disease progression
What is your clinical assessment of the patient's current condition?	Remission / Stable / Progression
What is the patient's current treatment outcome?	Maintained current treatment / Adjusted treatment plan / Further examination
How satisfied is the patient with their overall treatment experience?	Very satisfied / Fairly satisfied / Neutral / Not satisfied
Is the patient satisfied with their physical condition (e.g., physical strength)?	Very satisfied / Fairly satisfied / Neutral / Not satisfied
Is the patient satisfied with their psychological condition (e.g., anxiety levels)?	Very satisfied / Fairly satisfied / Neutral / Not satisfied
Is the patient satisfied with their cognitive function (e.g., memory and attention)?	Very satisfied / Fairly satisfied / Neutral / Not satisfied
Is the patient satisfied with their ability to reintegrate into social roles (e.g., work, social activities)?	Very satisfied / Fairly satisfied / Neutral / Not satisfied

P1.17.41 Bridging Gaps in Lung Cancer Care: The Quantitative Impact of Inter-Hospital Remote MDT Consultations in China

J. He[1], P. Cui[2], W. Gao[1]
[1]The First Affiliated Hospital of Nanjing Medical University, Nanjing/CN ,[2]VINTURA, Baarn/NL

Introduction: China's vast geography, socioeconomic diversity, and uneven healthcare distribution create disparities in lung cancer treatment. While many Tier 3 hospitals have advanced expertise and well-established multidisciplinary team (MDT) models, most Tier 2 hospitals face resource and knowledge limitations, negatively impacting patient outcomes. Remote inter-hospital MDT consultations help bridge this gap by integrating resources, improving diagnostic and treatment capabilities, and expanding access to quality care, particularly for rural patients. This study evaluates the impact of remote MDTs, their educational benefits, and best practices for broader implementation.

Methods: In 2024, 80 hospitals (11 Centers of Excellence [COE] and 69 Tier 2 hospitals) participated in inter-hospital MDTs through the iMDT digital platform, an AI-facilitated MDT management tool. A total of 302 healthcare professionals (HCPs) discussed 200 qualified lung cancer cases through remote MDT based on the platform. A structured questionnaire was distributed to HCPs to evaluate changes in treatment plans, improvements in diagnostic accuracy, and the perceived educational value of remote MDT participation. As of January 10, 2025, responses from 39 HCPs in 5 COEs and 194 HCPs in 69 Tier 2 hospitals were analyzed for insights on clinical and professional impact.

Results: Remote MDT consultations significantly improved lung cancer diagnosis, treatment decisions, and professional development. Following discussions with Centers of Excellence (COEs), treatment plans changed in 43% of cases (16% incorporating radiotherapy and ~10% adding immunotherapy) and the CRT rate increased significantly from 46% to 62%, demonstrating better alignment with standard care guidelines and broader adoption of comprehensive treatment strategies. Beyond clinical impact, remote MDTs were highly valued for professional development. 100% of healthcare professionals (HCPs) expressed satisfaction and willingness to continue participation, while 99% of Tier 2 hospital HCPs reported enhanced expertise. Additionally, 98% observed improvements in their hospital's diagnostic and treatment capabilities, reinforcing the role of remote MDTs in elevating care standards in lower-tier hospitals. These findings highlight the effectiveness of remote MDTs in optimizing treatment decisions, enhancing clinical expertise, and improving healthcare capacity in resource-limited settings.

Conclusions: Inter-hospital remote MDTs are an effective strategy for bridging the gap between Tier 3 and Tier 2 hospitals, improving diagnostic precision, treatment adherence, and HCP expertise. By facilitating real-time multidisciplinary discussions, digital platforms enable broader access to specialized lung cancer care while strengthening regional hospital capacity. To further reduce disparities and maximize impact, remote MDTs should be expanded to more regions, especially those with limited access to oncology expertise. Encouraging wider adoption will require stronger policy support, investment in digital infrastructure, and greater inter-hospital collaboration. Additionally, Hospitals could strengthen knowledge-sharing networks by sharing MDT resources, providing in-hospital training, and leveraging digital tools to enhance accessibility, efficiency, and long-term capacity building.

P1.17.42 Canadian Consensus Recommendations for Multi-Disciplinary Team Meetings in Lung Cancer Care

D. Dawe[1], H. Bahig[2], S. Burelle[3], C. Finley[4], D. Hao[5], S. Johnson[6], E. Leung[7], M. Manna[8], R. Myers[9], S. Najmeh[10], A. Pratt[11], B. Sheffield[12], A. Sun[13], R. Yuan[14], K. Forkheim[15], D. Manos[16], M. Kothari[17], M. Gallego-Llorente[18], M. Gomes[7]
[1]CancerCare Manitoba, Winnipeg/MB/CA ,[2]Centre Hospitalier de l'Université de Montréal, Montreal/QC/CA ,[3]Hopital Charles-LeMoyne, Greenfield Park/QC/CA ,[4]McMaster University, Hamilton/ON/CA ,[5]Tom Baker Cancer Centre, Calgary/AB/CA ,[6]Cross Cancer Institute, Edmonton/AB/CA ,[7]University of Ottawa, Ottawa/ON/CA ,[8]University of Saskatchewan, Saskatoon/SK/CA ,[9]University of British Columbia, Vancouver/BC/CA ,[10]McGill University, Montreal/QC/CA ,[11]Independent Patient Representative, Vancouver/BC/CA ,[12]William Osler Health System, Brampton/ON/CA ,[13]Princess Margaret Cancer Centre, Toronto/ON/CA ,[14]BC Cancer, Vancouver/BC/CA ,[15]Royal Jubilee Hospital, Port Coquitlam/BC/CA ,[16]Dalhousie University, Halifax/NS/CA ,[17]Vintura, London/GB ,[18]Vintura, Barcelona/ES

Introduction: Multi-disciplinary team meetings (MDTMs) are a key piece in the lung cancer care pathway, where healthcare providers collaborate on patient cases and decide on treatment plans. MDTMs increase adherence to guidelines and positively impact survival. MDTM preparation and follow-up are organized differently across hospitals and countries. These variations may lead to sub-optimal decision-making and outcomes. The increasing complexity of the diagnostic and therapeutic landscapes, importance of perspectives from multiple disciplines, and evolution towards patient-centered care emphasize the importance of MDTMs. The objective of this study was to understand current MDTM structures and practices in Canada, as well as develop a series of recommendations to improve MDTMs.

Methods: We created an MDTM Network with 15 representatives of Canadian lung cancer MDTMs across the country, including medical oncology, radiation oncology, thoracic surgery, respirology, pathology, nuclear medicine, nursing, radiology, and a patient representative. To develop insights, our framework of analysis focused on MDTM structure, including key process steps. An electronic survey was distributed, followed by one-on-one semi-structured interviews with each representative. A level of agreement of greater than 80% was considered consensus. Representatives then engaged in a face-to-face meeting to validate preliminary findings and discuss areas of uncertainty or disagreement.

Results: Within MDTM structure, the network identified core skills and disciplines that should be represented at each MDTM. Representatives agreed that MDTMs should be held at regular predefined intervals determined by center case volume, with a patient list circulated ahead of the meeting to allow time for preparation. Consensus on categories of patients who should always be discussed included but was not limited to patients with complex presentations, cases that do not fit standard of care, and patients that meet specific local criteria. Organizations can consider discussing all patient cases if resources allow. Representatives agreed that MDTM recommendations should be clearly documented in patient charts to facilitate communication with the entire healthcare team. The network understands MDTMs as the reification of a distributed community of practice (CoP), which is the multidisciplinary team (MDT). The MDTM is the regular event where healthcare professionals of an unstructured MDT providing care to lung cancer patients come together, clarifying the relationship between MDT and MDTM. Accordingly, we propose that Wenger-Trayner's CoP maturity model be used to assess MDT developmental stage in seven dimensions.

Conclusions: MDTMs are an essential part of the lung cancer patient journey. Any patient or healthcare professional involved in lung cancer management should have access to an MDTM. As MDTs and MDTMs are a standard part of patient care, recommendations focused on the details of how MDTMs operate are important to maximize the benefits of these collaborative efforts. Framing MDTs appropriately as communities of practice and fostering their growth can justify institutional resource allocation, enhance essential multidisciplinary representation, and could optimize both throughput of cases and patient outcomes. These recommendations support continuous improvement of MDTMs, ensuring they remain a cornerstone in patient management. Optimization of MDTMs should constitute a key part of the continuous improvement of the communities of practice they represent.

P1.17.43 Association Between Pretreatment Emotional Distress and EGFR-TKI Therapeutic Response in EGFR-Mutant Non-Small Cell Cancer

Z. Yang, Y. Xin
Fujian Medical University Union Hospital, Fuzhou/CN

Introduction: Association between pretreatment emotional distress and EGFR-TKI therapeutic response in EGFR-mutant non-small-cell lung cancer. Cancer patients frequently experience emotional distress (ED), typically presenting as anxiety and/or depressive symptoms. Experimental studies have indicated that ED may negatively influence the effectiveness of antitumor therapies. However, there is a lack of clinical research examining how ED may affect responses to EGFR-TKIs treatment.

Methods: Here we report results from a multicenter retrospective study,which investigated the association between ED and clinical efficacy of first-line treatment of EGFR-TKIs in patients with advanced EGFR-mutant lung cancer. ED was assessed by Patient Health Questionnaire-9 and Generalized Anxiety Disorder7-item scale.

Results: The study included 573 patients with 246(42.9%) exhibiting ED who presented depression(Patient Health Questionnaire-9≥5) and/or anxiety(Generalized Anxiety Disorder 7-item score≥5) symptoms at baseline. On the primary endpoint analysis, patients with baseline ED exhibited a significantly shorter median progression-free survival compared with those without ED(14.2 months versus 19.7 months, hazard ratio 1.70, 95% confidence interval 1.20 to 2.51, P=0.003). On the secondary endpoint analysis, ED was associated with lower objective response rate (75.1% versus 88.3%, odd ratio 0.37, P=0.031) and detriments in quality of life.

Conclusions: This study demonstrates that ED is associated with poorer clinical outcomes in advanced EGFR-mutation positive NSCLC patients receiving EGFR-TKI therapy, underscoring the importance of evaluating and managing ED as part of comprehensive cancer care.

[1]Fondazione IRCCS Istituto Nazionale dei Tumori, Milan/IT ,[2]Politecnico di Milano, Milan/IT ,[3]Mario Negri Institute for Pharmacological Research (IRCCS), Milan/IT ,[4]Laboratory of Integrative Cancer Immunology, Center for Cancer Research, NCI, Bethesda/MD/USA ,[5]University of Chicago, Chicago/IL/USA

Introduction: Multi-omics data represent a valuable source of biological insights to drive cancer research. While analyzing each omic layer independently remains effective, integrating multiple omic layers provides the greatest potential to characterize underlying biological processes. The PEOPLE (NCT03447678) trial is a multi-omic investigation designed to identify novel immune biomarkers in advanced non-small-cell lung cancer (aNSCLC) patients with negative or low PD-L1 expression, treated with first-line pembrolizumab.

Methods: Data were collected through multiparametric flow cytometry (FACS) in peripheral blood, transcriptomic profiling of tissue samples using the nCounter PanCancer IO 360 Panel (Nanostring), and gut microbiome taxonomic abundances via shotgun sequencing of stool samples. Transcriptomic counts were normalized using EdgeR package, converted into counts per million (CPM), and log2-tranformed. FACS counts and microbial relative abundances were log2-normalized to stabilize variance. The multi-omic integration was performed using MOFA2 package, generating 25 latent clusters. Survival analyses based on individual clusters were conducted. Gut microbiome data were further analyzed through network analysis using WGCNA package. Cluster loadings were analyzed to interpret their biological significance.

Results: Among 87 patients NSCLC patients screened, 65 patients were enrolled in the analysis with at least 1 available omic. 57, 48, and 54 patients had FACS, Nanostring, and microbiome data at baseline. Two clusters significantly stratified patient overall survival (OS). In cluster 5 all omics have a significant contribution to stratify OS (p = 00027). In particular, gene expression of CD79A, BLK, LTB, CD45RA, neutrophil CD15 high and leukocyte CD45+, Senegalimassilia anaerobia and Prevotella stercorea bacterias positively correlate with OS while gene expression of COL6A3, JAG1, Monocyte CD14+/HLADR+, Granulocyte CD16+ and Neutrophils 15+CD16+, Romboutsia timonensis, Clostridium saudiense) negatively correlates with OS. Cluster 6 two omics (FACS and gene expression) have significant contributions to stratify OS (0 = 0.0035). In particular gene expression of EIF2AK2 and different monocytes populations (intermediate $CD14^{+}CD16^{+}$, with or without high HLA-DR expression, non-classical $CD14dimCD16^{+}$, with or without HLA-DR expression) negatively correlate with OS. Network analysis of the gut microbiome revealed a more interconnected microbial network in patients with longer survival, consistent with findings in existing literature.

Conclusions: The present multiomics data integration methodology highlights the critical role of the interaction between host immunity specifically the microbiome and circulating immune profiles and tumor gene expression in predicting response to immunotherapy. Importantly, the approach also proved technically feasible in the presence of missing data, maintaining robustness across analyses. Notably, two distinct patient clusters were identified, indicating that pembrolizumab monotherapy may be effective in a subset of patients with low PD-L1 expression. This finding is particularly relevant for treatment de-escalation strategies, offering the potential to spare selected patients from chemotherapy and reduce treatment-related toxicity without compromising efficacy. The PEOPLE trial serves as a strong example of how prospective, biomarker-driven academic interventional studies should be designed to enable chemotherapy de-escalation.

P1.17.45 Multidisciplinary Digital Platform for Independent Adjudication of ILD/Pneumonitis Related to T-DXd Treatment

M.A. Fonseca Magalhães Filho[1], F. Marques da Costa[1], B. Costa da Silva[2], C.A. Leite[3], V. Cogo Destefani[4], A. Kreling Medeiros[1], M. Tenório Cerezoli[1], W. Nassib William Jr[5]
[1]Beneficencia Portuguesa de Sao Paulo, Sao Paulo/BR ,[2]Daiichi Sankyo Brasil, Sao Paulo/BR ,[3]Hospital Alvorada Brasília, Brasilia/BR ,[4]Universidade de Sao Paulo, Sao Paulo/BR ,[5]Grupo Oncoclinicas, Sao Paulo/BR

Introduction: Misdiagnosis or delayed diagnosis of T-DXd-associated ILD/p is common, contributing to increased morbidity and mortality. Access to pulmonologists and radiologists specialized in ILD/p remains limited in Brazil and globally. Our study aimed to evaluate the feasibility of a digital platform for independent adjudication and real-time management of suspected ILD/p cases through remote, asynchronous, multidisciplinary discussions.

Methods: Our platform consists of a secure phone/web-based app enabling referring physicians to upload anonymized clinical data and digital imaging. Pulmonologists, radiologists, and medical oncologists asynchronously discuss each case through a confidential, HIPAA-compliant chat. We analyzed data from the first 37 cases of suspected ILD/p submitted through the platform, assessing the ILD/p adjudication rate, time from submission to adjudication (TSTA), and time from submission to therapeutic plan formulation (TSTFT).

Results: Among the 37 submitted cases, 22 (59.5%) had clinical, radiological, and laboratory features consistent with ILD/p. Compared to pooled data from independent adjudication committees across nine phase I and II T-DXd studies (84.8% concordance), our observed concordance rate was 59.5%. Confirmed ILD/p cases were predominantly grade ≤2, with fewer grade 3 events. Median TSTA was 8.88 hours (range 0.05-86.53 hours), and median TSTFT was 11.65 hours (range 0.33-86.58 hours).

Conclusions: Implementing a digital platform for adjudication and management of suspected T-DXd-associated ILD/p was feasible and effective, with diagnostic rates consistent with those reported in clinical trials and timely adjudication and treatment decision-making. Approximately 40.5% of suspected ILD/p patients had alternative diagnoses, potentially allowing them to safely continue treatment. This approach could mitigate clinical challenges in regions lacking specialized ILD/p expertise.

P1.17.46 The Best Care One-Lung Program; a Pathway for Lung Cancer Screening in Primary Care

A. Hussey[1], C. Finley[2], M. Ferrone[1], C. McKenna Smith[3], R. Ormsby[3], A. Romanovschi[3], E. Phillips[3], A. Domik[1], F. Foster[1], C. Licskai[1,4]
[1]Asthma Research Group Windsor-Essex county Inc., Windsor/ON/CA ,[2]McMaster University, Hamilton/ON/CA ,[3]AstraZeneca, Mississauga/ON/CA ,[4]Western University, London/ON/CA

Introduction: Lung cancer screening of at-risk individuals by annual low-dose CT (LDCT) scanning reduces mortality, however, low rates of patient identification and referral limit access. In Ontario, Canada, primary care physicians (PCPs) are requested to identify and refer eligible patients, aged 55 to 74 with a 20-year smoking history, to the lung screening program. After referral, a regional cancer program navigator completes a risk assessment tool (PLCOm2012noRace) with the patient by telephone. Individuals with a ≥2%, 6-year, risk of developing lung cancer receive annual LDCT screening. Best Care is an established integrated chronic disease management program that embeds certified respiratory educator-case managers (CRE-CM) within primary care practices, to support PCPs to deliver guideline-concordant care. Chronic obstructive pulmonary disease (COPD) is one of the diseases that Best Care provisions. Exposure to tobacco smoke is a common risk factor for COPD and lung cancer, and COPD elevates lung cancer risk. We describe preliminary results from the Best Care One-Lung program, a new pathway in primary care that leverages the unique position of Best Care COPD, supporting PCPs in the identification, shared decision-making, and referral of high-risk individuals.

Methods: The Best Care One-Lung program was implemented in a pilot region (Hamilton, Ontario) in October 2024. Five CRE-CMs from 21 primary care practices identified patients aged 55 to 74 and with a 20-year smoking history from Best Care COPD (≈850 patients enrolled), primary care EMR searches, and PCP referrals. Eligible patients were invited to a Best Care One-Lung appointment led by CRE-CMs. Appointments included spirometry (if there was no existing COPD diagnosis), completion of the PLCOm2012noRace calculator, and for individuals with a lung cancer risk ≥2% shared decision-making and coordination of PCP referral to the screening program.

Results: Identified patients were predominantly from Best Care COPD with a confirmed COPD diagnosis. To date 586 individuals have been approached and 347 (59%) attended a One-Lung risk assessment (Figure1A). 234 (67%) were determined eligible for lung cancer screening (Figure 1B,1C) with a median risk of 5.4% equating to the potential detection of 13 lung cancers with 6 years of annual screenings (mean risk 7.1% SD(5.1)). LDCT scan results for 57 of the screened individuals included 5 scans reporting Lung-RADS assessment categories 4A,4B,or 4X (suspicious nodules).

Conclusions: The Best Care One-lung pathway to lung cancer screening is critically positioned to support primary care, identifying high-risk populations and improving access to life-saving screening.

Figure 1: Preliminary results from the Best Care One-Lung pathway to lung cancer screening in primary care

P1.17.47 Safety and Efficiencies of Specialist Lung Cancer Nurse-Enabled Pulmonary Nodule Management: An Australian Demonstration

V. Brunelli[1], J. Aflatooni[1], N. Shadbolt[2], H. Altenburg[2], S. Kochovska[2], D. Jeffery[3], S. Karipidis[3], K. Fleitmann[3], S. Sundar[3], A.C. Jones[3]
[1]University of Wollongong, Wollongong/AU ,[2]University of Wollongong, Graduate School of Medicine/AU ,[3]Wollongong Hospital, Illawarra Shoalhaven Local Health District, Wollongong/AU

Introduction: In July 2025, Australia will introduce a National Lung Cancer Screening Program (NLCSP). Specialist assessment and management of pulmonary nodules is a NLCSP aspect anticipated to have major implications on health workforce, resource utilisation and service delivery. April 2023, clinical redesign of a regional, public outpatients respiratory medicine specialist service in New South Wales, Australia, implemented a lung cancer nurse consultant to triage, undertake malignancy risk categorisation and subsequent clinical pathway management of patients referred for investigation of pulmonary nodules. This multipronged project aimed to understand the safety and efficiencies of nurse-enabled pulmonary nodule management. In project A, safety is defined as congruence between nurse and physician malignancy risk category and clinical pathway recommendation. In project B, efficiencies are defined as alignment of service delivery with Optimal Care Pathway for people with lung cancer critical time intervals.

Methods: Project A: Retrospective audit of a random sample of 33 nurse triaged referrals (post April 2023) were examined for congruence between nurse and physician nodule risk scoring and pathway recommendation. Descriptive statistics of e.g., clinical characteristics and comorbidities, proportion of incidental to screen detected nodules, informed the sensitivity analyses, which explored the accuracy of nurse risk categorisation (i.e., high/very high risk or non-urgent) by comparing nurse and physician risk scores and pathway recommendations (e.g., rapid access or surveillance), including patient outcomes over time. Instances of non-congruence between nurse and physician were examined. Project B: A retrospective audit of 30 high/very high-risk referrals (15 referrals pre-15 referrals post April 2023) with critical time intervals across patient clinical pathways (e.g., referral received by outpatients department to first specialist appointment, and more) examined between the two referred cohorts. The mean time in days for time intervals was calculated.

Results: Project A: In the high/very high-risk patient cohort, 12/18 (67%) had screen detected nodules; 9/15 (60%) of the non-urgent cohort were referred due to incidental nodules. In the non-urgent cohort, nurse malignancy risk categorisation was 100% congruent with physician risk scoring, yet congruence between subsequent clinical pathway recommendation was 53% (8/15 times congruent). Differences centred around patient complexities (e.g., pregnancy). In the high/very high-risk cohort, nurse malignancy risk categorisation was 83% (15/18) congruent with physician risk scoring and pathway recommendation. Despite a nurse guideline concordant approach to the assessment and recommendation of three patients, these were assessed by physicians as non-urgent. Project B: Post April 2023, the cumulative effect of time saved in the front-end steps of the clinical pathway represented a mean saving of 20 days (SD 9) from 'referral received to time to diagnosis'. Like the pre April 2023 data, post April 2023 patients who undergo bronchoscopy represented a longer time to diagnosis. The data suggest the nurse model increases the likelihood of high/very high-risk patients receiving curative intent treatment.

Conclusions: Specialist lung cancer nurse-enabled pulmonary nodule management is safe and offers patients a quality experience regarding the critical timeliness of their case management. The findings reinforce the need for an effective, multidisciplinary clinical governance framework in this advanced nursing practice context.

P1.17.48 Characteristics and Associated Survival of Patients Diagnosed With Non-Small Cell Lung Cancer in Western Kenya

A.L. MURUNGA
AMPATH-MOI TEACHING AND REFERRAL HOSPITAL, ELDORET/KE

Introduction: Advances in lung cancer treatment in high-income countries have significantly improved lung cancer patients' survival rates. Identification and treatment of driver mutations in lung cancer, such as EGFR, ALK, ROS-1, and others, have resulted in high response rates and notably extended survival in patients who harbor these mutations and receive molecular therapies. However, many of these treatment options have remained infrequently or entirely unavailable in Kenya and other low—and middle-income countries, significantly limiting survival in these patients. Improved data across the lung cancer care continuum including diagnostics and treatment are urgently needed to inform interventions that can improve lung cancer-related mortality in these regions. While lung cancer is a significant cause of mortality worldwide, studies in sub-Saharan Africa are scarce. Here we characterize outputs from a designated lung cancer program, part of the in western Kenya, part of the Multi-National Lung Cancer Control Program, which is focused on case finding, diagnosis, and treatment.

Methods: We retrospectively reviewed patients with pathologically confirmed non-small cell lung cancer (NSCLC) who enrolled in this program at Moi Teaching and Referral Hospital from January 2018 to December 2022. We analyzed clinical data using descriptive statistics, Kaplan-Meier methods, and a proportional hazards regression model.

Results: Two hundred forty-nine patients diagnosed with NSCLC were included with median age at diagnosis of 61(IQR 52-70) years. Most patients were married (177;73%) and non-smokers (177; 71) with 58 (23%) having received tuberculosis treatment and 93 (37%) having ECOG performance status of 2. At diagnosis, adenocarcinoma was the prominent histology (187;75%) along with clinical stage IV (195; 78% stage IV) or un-staged (40; 16%) disease. Most patients received chemotherapy and radiotherapy (176; 71%) with few palliative care referrals (2; 0.8%). Median overall survival (OS) was only 3.7 months (IQR 2.7-5.4). ECOG performance status (3 or 4) and being un-staged were predictors of poor 1-year OS.

Conclusions: Patients with NSCLC enrolled in this program presented with advanced disease and poor survival. Despite a designated case-finding effort, late diagnosis remained common and highlights a need for locally relevant interventions targeting community and provider education as well as timely and innovative diagnosis that can improve early recognition of lung cancer in Kenya. These interventions must also be paired with access to diagnostics and associated treatments including molecular therapies and palliative care which can extend lung cancer survival.

P1.17.49 Real-World Outcomes With IO and Chemo-IO Demonstrate Unmet Need for 1L KRAS G12C-Mutant Advanced NSCLC in the US

K. Sheffield[1], T. Puri[1], K. Thoele[1], H. Karu[1], A. Mansharamani[1], D. Uprety[2]
[1]Eli Lilly and Company, Indianapolis/IN/USA ,[2]Karmanos Cancer Institute, Detroit/MI/USA

Introduction: While KRAS G12C mutations are fairly common amongst US patients with NSCLC, there are no approved 1L treatments directed at KRAS mutations. Current 1L options are commonly immunotherapy (IO) alone or with platinum-based chemotherapy (PBC). We evaluated clinicopathologic characteristics, treatment patterns, and outcomes among patients with KRAS G12C-mutant advanced NSCLC.

Methods: This retrospective study included patients with advanced NSCLC who initiated 1L treatment from 8/1/2018-12/31/2022 and had KRAS test results. The US-based deidentified Flatiron Health-Foundation Medicine NSCLC Clinico-Genomic database (CGDB) and Flatiron Health Research database were queried. These are longitudinal, comprising patient-level structured and unstructured data. Patients were evaluated by KRAS mutation status: KRAS G12C-mutant, other KRAS-mutant, KRAS wild-type (with driver alteration and without driver alteration). Progression-free survival (PFS), time-to-treatment discontinuation (TTD), and overall survival (OS) were estimated using Kaplan-Meier methods and Cox proportional hazards models.

Results: In the CGDB, 447(11.9%) patients had KRAS G12C-mutant, 657(17.4%) had other KRAS-mutant, and 2,664(70.7%) had KRAS wild-type NSCLC. Most patients with KRAS G12C-mutant NSCLC had non-squamous carcinoma (92.0%), were treated in community practice (88.1%), and had a history of smoking (98.7%). The prevalence of brain metastasis at diagnosis of advanced disease was higher among patients with KRAS G12C-mutant (25.1%) and other KRAS-mutant (25.7%) than KRAS wild-type NSCLC (20.9%; p=0.008). In the KRAS G12C-mutant cohort, PBC+pembrolizumab was the most common regimen (46.1%) regardless of PD-L1 status. Pembrolizumab monotherapy was most common (36.8%) in the PD-L1 ≥50% subgroup. Among patients who received 1L treatment, 37.4% received 2L therapy. Median PFS and OS for patients with KRAS G12C-mutant NSCLC treated with PBC+pembrolizumab were 5.3 and 12.8 months, respectively. In adjusted Cox proportional hazards models for patients treated with PBC+pembrolizumab, patients with other driver mutations had significantly longer PFS and OS compared to patients with KRAS G12C mutations. No significant differences were observed among patients treated with pembrolizumab monotherapy. In the Research database, 1,227(10.0%) patients had KRAS G12C-mutant, 1,821(14.8%) had other KRAS-mutant, and 8,830(71.9%) had KRAS wild-type NSCLC. Median TTD and OS for patients with KRAS G12C-mutant NSCLC treated with PBC+pembrolizumab were 5.5 and 15.6 months, respectively, and with pembrolizumab monotherapy were 5.0 and 22.1 months, respectively.

Conclusions: Real-world evidence suggests patients with KRAS G12C-mutant NSCLC have shorter PFS and OS compared to those with KRAS wild-type, when treated with PBC+pembrolizumab. Additionally, most patients with KRAS G12C-mutant NSCLC never received 2L therapy. These data highlight the need for more effective 1L therapies for KRAS G12C-mutant patients.

CGDB	N	Median PFS (months) Adjusted HR, p-value	Median OS (months) Adjusted HR, p-value
PBC+pembrolizumab PD-L1 all comers

P1.17.50 Correlation Between Clinical and Pathological Stage in Resected NSCLC

G.F. Cittolin Santos, B. Knapp, S. Tohmasi, M.E. Flanagan, V. Puri, R. Govindan, D. Morgensztern, W. Brandt, J. Ward
Washington University in St Louis, St Louis/MO/USA

Introduction: Accurate clinical staging is critical for guiding treatment decisions in patients (pts) with resectable non-small cell lung cancer (NSCLC), particularly as neoadjuvant therapy becomes more widely utilized. While adjuvant therapy is based on the pathological staging, neoadjuvant therapies rely on the clinical staging. This study assessed the correlation between clinical (c) and pathological (p) staging in surgically resected NSCLC.

Methods: We queried the National Cancer Database (NCDB) for patients diagnosed with NSCLC between 2004 to 2020 who underwent upfront surgical resection with documented cTNM and pTNM staging. Pts with stage IV, missing data, or who received neoadjuvant therapy were excluded.

Results: Among the 325,794 eligible pts, clinical stages I, II, and III accounted for 78.3%, 14.9%, and 6.8% of pts, respectively. Pathological staging was 67.1% stage I, 19,9% stage II, 12.3% stage III, and 0.6% stage IV. Overall clinical to pathological TNM were downstaged in 4.0%, upstaged in 17.4%, and concordant in 78.6% of the cases. T stage was concordant in 76% of cases, downstaged in 4% and upstaged in 19% while N stage was concordant in 84% of cases, downstaged in 3% and upstaged in 13%. Patients with cN0, cN1 and cN2 had concordant pathological stages in 86.6%, 63.6% and 63.5% respectively. pN2 was seen in 4.7% of cN0 and 15.3% of cN1. Among pts with cN2, 24.4% had pN0, 11.7% pN1 and 0.4% pN3. While cN2 is downstaged to pN0 in 24.4% and to pN1 in 11.7% of cases, there are more pN2 cases overall than cN2 due to upstaging from cN0 and cN1 to pN2 (Table). Factors associated with staging discordance included female gender, Black race, squamous cell carcinoma histology, ≥ 5 lymph nodes sampled intraoperatively, pneumonectomy, treatment at non-academic centers, and a delay of > 30 days from diagnosis to surgery.

Conclusions: Significant discrepancies exist between clinical and pathological stages in real-world practice. Optimizing staging is critical to decrease the clinical and pathological staging discordance, and allow better treatment selection in resectable pts.

Table. Frequency of clinical and pathological staging

	Clinical	Pathological	Concordant	Upstage	Downstage
Stage I	255,018 (78.3%)	218,776 (67.1%)	81.9%	18.1%	-
Stage II	48,520 (14.9%)	64,859 (19.9%)	64.6%	20.9%	14.5%
Stage III	22,256 (6.8%)	40,232 (12.3%)	71.0%	1.8%	27.3%
Stage IV	0	1,927 (0.6%)	-	-	-
T1	207,503 (63.7%)	167,275 (51.3%)	75.8%	24.2%	-
T2	90,894 (27.9%)	115,965 (35.6%)	78.1%	12.7%	9.2%
T3	20,367 (6.3%)	31,910 (9.8%)	73.1%	7.5%	19.4%
T4	7,030 (2.2%)	10,644 (3.3%)	72.4%	-	27.6%
N0	289,537 (88.9%)	258,854 (79.5%)	86.6%	13.4%	-
N1	23,478 (7.2%)	41,390 (12.7%)	63.6%	15.4%	21.0%
N2	12,779 (3.9%)	25,385 (7.8%)	63.5%	0.4%	36.1%
N3	0	165 (0.1%)	-	-	-

P1.17.51 Real World Outcomes of Metastatic Mucinous Adenocarcinoma of Lung

D. Karam Prasad[1], A. Sridhar[2], Y.C. Lo[1], A. Singh[3], A. Dimou[1], K. Parikh[1], M. Shanshal[1], J. Molina[1], A. Mansfield[1], K. Smith[1], A. Luce[1], A. Schwecke[1], R. Manochakian[1], K. Leventakos[1]
[1]Mayo Clinic, Rochester/MN/USA ,[2]UT Southwestern Medical Center, Dallas/TX/USA ,[3]VA Medical Center, Minneapolis/MN/USA

Introduction: Mucinous adenocarcinoma is a distinct entity among patients with lung cancer, with the diagnosis made both pathologically and radiologically. It is a rare disease with varying treatment patterns and outcomes globally. The aim of our multi-site single center retrospective study was to describe the unique clinicopathologic and genetic features of metastatic invasive mucinous adenocarcinoma (MIMA) of lung origin, also describe the treatment patterns and survival outcomes.

Methods: We analyzed data from 160 patients with MIMA, treated at Mayo Clinic Comprehensive Cancer Center (MCCCC) from Jan 2010 until Dec 2023. The clinical and radiologic findings were confirmed by 2 independent reviewers prior to inclusion of patients in our cohort. Data analysis was performed with Blue sky statistics (v 10.4).

Results: The median age at diagnosis was 68.5 years and our cohort included 56 patients with a confirmed diagnosis of Stage IIIC or IV MIMA. About 77% of patients had a smoking history. Pathology of mucinous adenocarcinoma was was made by features of abnormal glandular cells with presence of abundant intracelllular or extracellular mucin. Commonly analyzed pathologic markers included CK-7 (33%), CK-20 (15%), napsin (5%) and mucicarmine (3%). Less frequently analyzed pathologic markers were MUC 2, MUC 6, CDH1 and 2, PAX 8 and CDX 2. Targetable genetic alterations seen included KRAS [39%, KRAS G12D (20%), KRAS G12V (17%)], ALK, EGFR, ROS1, MET (2.5%), and RET, TP53, STK11, BRAF, IDH2, CHEK2, CDKN 1A/B, ERBB2, ARID1 oncogenic alterations (1%). NRG1 mutations were not observed in our cohort. 54% patients were treated with chemoimmunotherapy (Table 1). Median progression Free Survival for patients treated with chemoimmunotherapy Vs other therapy was 8.15 months Vs 8.18 months respectively (p=0.8). There was no difference in median overall Survival for patients who received first line chemoimmunotherapy vs other therapy 19.2 Vs 19 months (p=0.8). OS was lowest in current smokers at 12.5 months, followed by past-smokers at 13.8 months and was higher in non-smokers at 33.3 months (p=0.1).

Conclusions: This is the first real-world study assessing the outcomes in patients diagnosed with metastatic MIMA in the precision medicine era. It is interesting to note that survival outcomes do not differ much in patients who received chemoimmunotherapy vs other therapies highlighting the aggressive nature of this disease. The unique and distinct nature of this disease highlights the need for further research to identify pathways for precision medicine for MIMA.

Table 1: First line regimens used to treat MIMA of lung origin:

Name of Regimen	Genetic alteration targetted for therapy	Percentage of patients (N=56)
Carboplatin Pemetrexed Pembrolizumab	NA	54%
Carboplatin Paclitaxel Atezolizumab	NA	2%
Carboplatin Pemetrexed Cemiplimab	NA	2%
Pembrolizumab Datopotamab Deruxtecan	NA	2%
Pembrolizumab	NA	2%
Carboplatin Pemetrexed	NA	6%
Carboplatin Gemcitabine	NA	2%
Carboplatin Paclitaxel	NA	2%

P1.17.52 Real-World Treatment and Survival in KRASG12C-Mutated Locally Advanced/Metastatic Non-Small Cell Lung Cancer in England

A. Greystoke[1], A. Lee[2], G. Emanuel[2], C. Rault[3], L.J. Eccles[4], S. Rizzi[5], B. Correia[6], M. Mella[7], E. Markov[8], G. Georgakis[9], J. Jesus[10], M. Glassberg[4], S. Paaske Johnson[11]
[1]Newcastle Hospital and Newcastle University, Newcastle Upon Tyne/GB ,[2]Bristol Myers Squibb, Uxbridge/GB ,[3]Data Gnosis, Rennes/FR ,[4]Bristol Myers Squibb, Princeton/NJ/USA ,[5]IQVIA Ltd, Copenhagen/DK ,[6]IQVIA Ltd., Porto Salvo/PT ,[7]IQVIA Ltd., Milan/IT ,[8]IQVIA Ltd., Sofia/BG ,[9]IQVIA Ltd., Chalandri/GR ,[10]IQVIA Ltd., Lisbon/PT ,[11]Danish Center for Health Services Research, Department for Clinical Medicine, Aalborg University & Aalborg University Hospital, Aalborg/DK

Introduction: With the advent of immunotherapies and novel targeted therapies, the treatment landscape for locally advanced/metastatic (LAM) non-small cell lung cancer (NSCLC) has evolved rapidly, necessitating real-world evaluations of treatment patterns and effectiveness to guide therapeutic decision-making. As a part of the international I-O Optimise initiative, this study aimed to characterize treatment patterns and survival in patients with KRASG12C-mutated LAM NSCLC in England using the Cancer Analysis System database.

Methods: This historical study included adult patients (≥18 years) with de novo or recurrent LAM NSCLC. Two cohorts were established: (1) patients receiving sotorasib who were assumed to harbor the KRASG12C mutation due to the drug indication (sotorasib cohort) and (2) patients with confirmed KRASG12C mutation, receiving a second or later lines of treatment (2L+ cohort). The overall study period spanned from January 2014 to October 2023, encompassing NSCLC diagnoses from 2014-2021, KRASG12C mutation testing from 2016-2021, and treatment data collection through 2023. Treatment sequences were identified algorithmically and will be presented using Sankey diagrams. The kaplan-Meier method was used to estimate overall survival (OS) from the start of sotorasib or a second-line treatment for the sotorasib and 2L+ cohorts, respectively.

Results: The sotorasib and 2L+ cohorts included 240 and 141 patients, respectively. In the sotorasib cohort, 67.1% were female, median age was 69 years at inclusion date, and 92.5% had an Eastern Cooperative Oncology Group performance status (ECOG PS) ≤1. In the 2L+ cohort, 59.6% were female, median age was 69 years at inclusion date, and 87.9% had an ECOG PS ≤1. In the sotorasib cohort, the most common treatments were anti-programmed death-1 (PD-1)/programmed death ligand 1 (PD-L1) immune checkpoint inhibitors (ICIs) plus platinum-based chemotherapy in first line and tyrosine kinase inhibitors (TKIs) alone (predominantly sotorasib) in second and third line (Table). In the 2L+ cohort, the most common treatments were platinum-based chemotherapy in first line, anti-PD-1/PD-L1 ICI monotherapy in second line, and docetaxel ± nintedanib in third line (Table). Median OS in the sotorasib and 2L+ cohorts were 13.1 and 12.4 months, respectively. Median OS in the 2L+ cohort by type of second-line treatment received ranged from 9.2 months with anti-PD-1/PD-L1 ICI monotherapy to 15.1 months with TKIs.

Conclusions: These real-world results from England provide insights on the adoption of KRASG12C inhibitors into routine clinical practice as second or later lines of therapy for patients with KRASG12C-mutated LAM NSCLC and the associated survival outcomes.

Type of systemic anticancer treatment, n (%)	Sotorasib cohort (n = 240)	2L+ cohort (n = 141)
First line

P1.17.53 Real-World Experience With EGFR-Positive NSCLC in Resource-Limited Settings: A Decade-Long Single Center Study From Jordan

K.H. Al-rabi[1], A. Yaseen[2], M. Ma'koseh[2], O. El Kahtib[2], H. abu jazar[2], S. Yaser[2], A. Al-Ibraheem[2], O. Younis[3], Y. Talab[2], y. Hamadneh[3], A. Zayed[2]
[1]KHCC, amman/JO ,[2]king Hussien cancer center, amman/JO ,[3]University of Jordan, amman/JO

Introduction: Real-world evidence for EGFR TKI outcomes in Jordan and the Middle East is limited. While the use of third-generation TKIs first-line has become the standard, first-generation TKIs use is common here. This study evaluate the outcomes of EGFR-positive NSCLC over the last 10 years at King Hussein Cancer Center

Methods: This retrospective study analyzed data from 200 patients diagnosed with EGFR-positive NSCLC at King Hussein Cancer Center (KHCC) between 2014 and 2024. Data were extracted from electronic medical records, including demographics, clinical characteristics, molecular testing results, treatment regimens, responses, and survival outcomes. Descriptive statistics summarized baseline characteristics. Kaplan-Meier analysis estimated overall survival (OS) and progression-free survival (PFS). Cox regression analysis identified predictive factors for treatment response and survival outcomes.

Results: The study included 200 patients with median follow up of 26.8 (21-33.6)months, Clinical characteristics included median age 61.2 (29-91.6) years, female 103/200 (51.5%), never-smoking 129/200(61,4%), Exon 19/L858R 114/200 (57%) 71/200 (35.5%) , brain metastasis at diagnosis in 90/200 (45.0%) patients , Gefitinib was most common first line in 150 (75%) , followed by chemotherapy 33 (16.5%), Osimertinib used in 9 (4.5%). the most common second line was Osimertinib in 52 (43.0%), followed by chemotherapy in 31 (25.6%).Median PFS for Gefitinib in the first line was 10 [95%CI:8-13]months, median PFS for Gefitinib and Osimertinib at any line was 10 [95% CI:8 - 12] months and 14 [95% CI:7 - 21] months respectively ,the median overall survival was 25 [95% CL:19 - 31] months for all patients who received TKI in any line .Factors contributing to worse OS in the multivariate model were liver metastasis and PD-L1 >50% , HR 1.78 (1.08-2.91, p=0.022) and HR 1.74 (1.01-3.00, p=0.045) respectively .

Conclusions: Jordanian patients with EGFR mutated lung cancer treated with any TKI have long survival consistent with published literature. Liver metastasis at diagnosis and high PD-L1 expression were associated with worse survival. Access to third and newer generation TKI is critical

Introduction: The use of first-line single agent immunotherapy in patients with advanced NSCLC and ECOG PS ≥2 remains controversial, as this frail population has been largely excluded from pivotal clinical trials. Real-world evidence suggests that although median survival is poor, a subset of these patients may achieve long-term benefit.

Methods: We analyzed data from the Pembro-Real 5Y registry, a global real-world dataset with >5 years follow-up. The cohort included patients with advanced NSCLC, PD-L1 TPS ≥50%, treated with first line pembrolizumab outside of clinical trials. Univariable analyses were conducted to identify descriptive characteristics associated with survival. To address the complexity of long-term outcome prediction, we integrated Elastic Net regression and a transformer-based AI model (NAIM). The Elastic Net model was employed to mitigate collinearity and select relevant prognostic factors, while NAIM was used to explore non-linear, time-dependent interactions between variables. Endpoints included overall survival (OS) and 5-year survival rates.

Results: Out of 1050 patients, 161 patients with ECOG PS ≥2 were included, showing a median OS of 5.4 months (95% CI: 3.8-7.8), and a 5-year survival rate of 13.0% (95% CI: 8.1-19.9) (Figure). Univariable analysis indicated that no single baseline variable was associated with the 5-year survival, except for TMB (p=0.01), KRAS (p=0.01), and BRAF status (p=0.02), which were significantly limited by missingness. Elastic Net identified only two significant predictors of 5-year survival: high TMB (with unstable confidence intervals, OR 7.09×10^{8}, 95% CI: 0.00-∞ and KRAS mutation (OR 3.04, 95% CI: 1.08-8.27). NAIM provided a dynamic perspective, confirming that bone metastases and baseline corticosteroid use were strong predictors of early mortality, whereas BMI increase and systemic health markers/host factors (e.g., hypertension and dyslipidemia) gained importance in long-term survivors (Figure). However, NAIM exhibited a notable performance drop from training to validation suggesting overfitting and the challenge of modeling long-term outcomes using baseline static variables.

Conclusions: Despite the overall poor prognosis, a subset of patients with ECOG PS ≥2 achieves long-term survival with pembrolizumab monotherapy, indicating that performance status alone should not preclude treatment in all cases. Our analysis highlights the limitations of traditional statistical approaches and AI-driven models in predicting long-term benefit in this heterogeneous population. Future efforts should focus on refining hybrid modeling strategies and incorporating prospective validation to better identify those who may benefit from immunotherapy beyond short-term expectations.

Introduction: Older adults patients represent a growing proportion of individuals with advanced NSCLC. Long-term survival in this population is particularly challenging to assess due to the complex interplay of aging, comorbidities, and immunotherapy outcomes. Traditional statistical approaches may fail to capture the granular effects of age and systemic health factors, underscoring the need for more advanced methodologies.

Methods: We analyzed data from the Pembro-Real 5Y registry, a global real-world dataset of 1,050 patients with advanced PD-L1 ≥50% NSCLC treated with first-line pembrolizumab across 61 institutions in 14 countries. The dataset features over 5 years of follow-up and includes 36 baseline variables. To identify predictors of overall survival (OS) and 5-year survival, we applied Elastic Net regressions with multiple imputation by chained equations (MICE) to account for missing data and collinearity. To enhance interpretability and better capture the nuanced role of age, we employed the NAIM approach, a novel transformer-based AI model capable of handling missing data without imputation. Model explainability was provided via SHAP values.

Results: Increasing age was significantly associated with a higher risk of death (HR 1.01, 95% CI: 1.00-1.02) and lower 5-year survival rate (OR 0.98, 95% CI: 0.97-0.99) in the Elastic Net regression model. In the NAIM analysis, which achieved an AUC of 60.5 ± 3.7 for 5-year survival and a C-index of 62.9 ± 2.1 for OS, SHAP values ranked age as the 7th most important variable for 5-year survival and the least important for OS among the 36 variables. When stratified by age groups (<60 years [n=249, 23.7%], 60-80 years [n=703, 67.0%], >80 years [n=98, 9.3%]), the prioritization of variables influencing OS was consistent across groups. Predictors such as poor ECOG-PS (≥2), exposure to steroids, bone metastases, male sex, higher BMI, and smoking status emerged as key factors. For 5-year survival, systemic health markers (e.g., absence of hypertension or cardiovascular comorbidities), dysmetabolic factors (e.g., dyslipidaemia, increasing BMI), and the absence of bone metastases dominated across all age groups. Notably, good ECOG-PS was the strongest predictor in patients aged >80 years.

Conclusions: This study emphasizes the importance of a multidimensional approach to long-term prognostication also in older adults with advanced NSCLC undergoing immunotherapy. The NAIM analysis underscored the diminishing standalone importance of age and highlighted the critical role of systemic health factors across all age groups. These findings advocate for comprehensive assessments that integrate functional status and comorbidities irrespective of chronological age.

P1.17.56 Clinical Features and Outcomes of Lung Cancer in Young Patients

B. Xu, J. Guan, X. Tian, H. Chen
Guangdong Provincial People's Hospital (Guangdong Academy of Medical Sciences), Southern Medical University, Guangzhou/CN

Introduction: Lung cancer is the leading cause of cancer-related death worldwide and shows a tangible trend of rejuvenation. Nevertheless, data focusing on young patients with lung cancer is rare. This study aimed to present clinicopathologic characteristics and treatment outcomes of young patients with lung cancer.

Methods: Lung cancer patients less than 40 years old at the time of diagnosis were retrospectively collected between October 2021 to April 2024. Demographic data, clinical efficacy, gene profiles and survival outcome were collected during the treatment.

Results: 230 eligible patients were retrospectively collected, 111 males and 119 females, median age 37years old (range: 14-40years), and 83% of them were non-smoker. Most of the population were found stage IV disease (76.5%) or stage III disease (16.5%) at baseline, 15.7% of them were diagnosed during health examination, the others usually presented with nonspecific respiratory symptoms such as cough (41.3%), chest tightness (17.0%) and polypnea (12.2%). As for the histology, 80.9% were adenocarcinoma, 4.8% were squamous carcinoma, 5.2% were lymphoepithelioma, 2.2% were small cell carcinoma and 5.2% were other rare types. Most of the population were driver gene positive (74.8%), with 33.5% EGFR mutation, 25.2% ALK fusion, 5.7% ROS1 fusion, 3.9% RET fusion and 6.5% others. For EGFR sensitive mutant patients, the objective response rate (ORR) for first line EGFR-TKI was 61.67%, the median progression free survival (PFS) was 14.4months (95%CI: 10.1-18.7months), with 15.4months for 19del and 9.8months for L858R. For ALK fusion patients, the ORR for first line ALK-TKI was 73.10%, the median PFS was 22.0months (95%CI: 14.7-29.2months). For patients who received chemotherapy or chemotherapy plus immunotherapy as first line, the ORR was 31.40%, the median PFS was 10.1months (95%CI: 7.5-12.8months), with 9.7months for adenocarcinoma, 16.5 months for squamous carcinoma and 7.6months for other types of histology.

Conclusions: Young patients with lung cancer were presented with atypical symptoms and often diagnosed at advanced stage. Adenocarcinoma accounted for higher proportion and rare driver gene mutations were more common in young patients. The treatment outcome for young patients were similar with the overall population, but the PFS was obviously shorter for ALK fusion young patients.

P1.17.57 Estimates of Clinical Endpoints in Matched Patients Between the French Cancer Cohort (FCC) and Durvalumab Stage III NSCLC Eap

I. Charkaoui[1], M. Narbeburu[1], M. Licour[2], V-P. Luu[3], C. Morgand[1], C. Le Bihan[1], N. Ozan[4]
[1]Institut national du cancer, Boulogne/FR ,[2]OncoReal, Fontenay-Sous-Bois/FR ,[3]Former Artificial Intelligence and Cancers association, Paris/FR ,[4]AstraZeneca France, Courbevoie/FR

Introduction: Early Access Program (EAP) are an opportunity to document first use of innovative treatments in real-world settings. Since 2021, French HTA body has recommended a linkage of EAP with National Health Data System (NHDS), the French health claims database.

Objective: to investigate if FCC, an NHDS extract of patients (pts) with cancer, can substitute a follow-up EAP study to estimate Overall Survival (OS) and treatment duration; and to evaluate if time to first subsequent therapy or death (TFST) can be used as a Progression Free Survival (PFS) proxy.

Methods: Indirect deterministic linkage was performed between :1/ French EAP follow up study of locally advanced unresectable NSCLC pts who initiated durvalumab between Oct.1 2017 and Dec. 31 2018, and treated up to 12 months (n=342); 2/ pts from FCC who received durvalumab at time of EAP (n=666).

In FCC, clinical outcomes such as disease progression can only be approximated by reported healthcare consumptions. All endpoints were calculated from first durvalumab administration date and up to last pt contact for EAP, Nov.30 2020 for FCC. First and last administration dates were reported in EAP vs each injection in FCC.

Results: 278 matched pts were included in analyses (linkage rate=81.4%). Median [IQR] EAP follow up was 747.5 [550;822] days vs. 812.5 [545;895] days in FCC. Discordances were limited in first and last durvalumab administration dates between EAP and FCC: in 51 pts (18.3%) for first date and in 35 pts (12.6%) for last date (median difference FCC-EAP: 47 [28;83] days and -1 [-28;14] day respectively).

81/82 deaths in EAP were reported in FCC with death date equal +/- 1 day in 75 (91.5%). OS 1- year (87.1% in both sources) and 2-years (71% and 70.8%) rates in EAP and FCC fully overlap (Table 1).

Treatment duration was longer in EAP (median 328.5 [274;346] days vs 295 [242;323] days in FCC).

Although TFST in FCC is close to PFS in EAP at 2 years (Table 1), TFST rates are not consistent between the 2 sources (+21 events in FCC).

Conclusions: Estimates of OS are aligned between the 2 sources and confirm the interest to use NHDS to document OS in a real-world setting. EAP treatment duration can be underestimated in FCC since free-of-charge treatment like compassionate use are not recorded. No evidence was found to use TFST in NHDS as a PFS proxy. Studies with longer follow up will be needed for this evaluation.

Table 1

	OS		PFS	TFST	
	EAP	FCC	EAP	EAP	FCC
N° events / N° pts	82 / 278	87* / 278	140 / 278	122 / 278	143 / 278
Rate 1 year (%) [95% CI] $	87.1 [85.0-89.1]	87.1 [85.0-89.1]	63.2 [60.3-66.1]	70.5 [67.8-73.2]	68.7 [65.9-71.5]
Rate 2 years (%) [95% CI] $	71.0 [68.3-73.8]	70.8 [68.0-73.5]	51.5 [48.4-54.6]	56.9 [53.9-59.9]	52.8 [49.8-55.8]

P1.17.58 Real-World (RW) Study of Biomarker Testing Patterns Among Patients With Early-Stage Resected NSCLC in the United States

S. Patel[1], R. Hsu[2], M. Shiller[4], E. Baser[5], T. Habib-Ishaq[5], M. Lupicka[5], Y. Rattigan-Brown[5], M. Stokes[6], R. Ghosh[7], C. Pettersson[8], Y. Liang[5], M. Sandelin[9], R. Jean-Baptiste Salomonsen[5]
[1]UC San Diego, San Diego/CA/USA ,[2]University of Southern California, San Diego/CA/USA ,[4]PathGroup, Nashville/TN/USA ,[5]AstraZeneca, Gaithersburg/MD/USA ,[6]Evidera PPD, Bethesda/MD/USA ,[7]Evidera Data Analytics, Bethesda/MD/USA ,[8]Evidera PPD, Stockholm/SE ,[9]AstraZeneca, Uppsala/SE

Introduction: Molecular diagnostics are increasingly important for patients with resected early-stage NSCLC as trials have demonstrated improved survival with biomarker-targeted adjuvant treatments and neoadjuvant/perioperative chemoimmunotherapy. We evaluated biomarker testing patterns in the US setting using Flatiron Health data.

Methods: Patients with stage IB-IIIB (T3N2) NSCLC diagnosed during 2021-2023 who had surgical resection were included. Biomarker testing rates (EGFR, ALK, and PD-L1), time from diagnosis to test date, turnaround time (time from test date to results) and time from biomarker test results to adjuvant treatment were evaluated overall and by stage and sociodemographic characteristics (age, gender, region, socioeconomic quintile [Q], and race).

Results: In this cohort (N=885), we observed increased molecular biomarker testing over time (1H2021: EGFR 62% ALK 54% vs. 2H2023: EGFR 77% ALK 69%) (p<.05). However, only 26.7% were tested prior to surgery. Neoadjuvant testing rates were stable during the study period (1H2021: EGFR 21% ALK 21% PD-L1 26% vs. 2H2023: EGFR 20% ALK 17% PD-L1 26%). Patients in the West were more likely to receive neoadjuvant PD-L1 (40.0%) tests versus the South (PD-L1: 22.8%), Midwest (PD-L1: 17.6%), and Northeast regions (PD-L1: 21.3%) (p<.05). Higher proportions of patients in the highest socioeconomic quintiles received PD-L1 tests (Q4/Q5: 78.9%) versus the lowest quintiles (Q1/Q2: 66.7%) (p<.05). Stage IIIB patients were more likely to receive EGFR (79.3% vs. 64.4%), ALK (75.9% vs. 48.3%), and PD-L1 (89.7% vs. 73.8%) tests following diagnosis versus Stage IB (p<.05). We saw numerically shorter times from diagnosis to biomarker testing for Black (11.4 days) versus White (20.5 days) and Hispanic/Latino (21.8 days) patients and those in the top 2 socioeconomic quintiles (Q4/Q5: 16.2 days) versus the lowest quintiles (Q1/Q2: 24.8 days). Among patients receiving adjuvant treatment (539/885), 90.5% received at least one test prior to treatment. Testing was highest for PD-L1 testing (82.2%), followed by EGFR (79.8%), and ALK (67.9%). Most EGFR tests were conducted using next generation sequencing (NGS) (85.9%) while ALK relied on NGS (59.4%) and FISH (30.5%). Turnaround times for EGFR tests administered before adjuvant treatment were shorter for PCR (28.6 days) versus NGS (45.3 days) (p<.05) and shorter for FISH (32.1 days) versus NGS (50.6 days) for ALK (p<.05). However, NGS tests for EGFR and ALK had shorter times from results to adjuvant treatment compared to other testing methods. Turnaround times for any biomarker were numerically shorter for Stage IIIB (31.9 days) vs. IB (43.6 days).

Conclusions: We found lower rates of PD-L1 testing and longer times from NSCLC diagnosis to biomarker test dates in patients in the lowest two SES quintiles. Biomarker testing was more prevalent and with shorter turnaround times in stage IIIB versus stage IB, and shorter for PCR/FISH testing versus NGS. We observed low rates of biomarker testing in the neoadjuvant setting. Significant regional differences were observed with the West having higher neoadjuvant PD-L1 testing rates. Improving turnaround times in NGS testing and understanding reasons behind socioeconomic disparities are keys to better biomarker testing outcomes in early stage NSCLC.

P1.17.59 Real-World Uptake of Immunotherapy for Stage III-IV Non-Small Cell Lung

Cancer: Insights From the National Cancer Database (2016–2021)
S. Kalantri[1], T. Jones[1], J. Freeman[2], B. Morguelan[1], M. Kong[1], G. Kloecker[1]
[1]Brown Cancer Center, University of Louisville, Louisville/KY/USA ,[2]The University of Chicago, Chicago/IL/USA

Introduction: The introduction of immune checkpoint inhibitors (ICIs) has transformed treatment for Stage III-IV lung cancer, yet real-world adoption and access remain unclear. Landmark trials, e.g., KEYNOTE-024 (2016), PACIFIC (2017), and CheckMate 227 (2019), established ICIs as standard of care in various non-small cell lung cancer (NSCLC) settings. We examined trends and variations of immunotherapy utilization using the National Cancer Database (NCDB), a hospital-based registry capturing >70% of new U.S. cancer cases.

Methods: This retrospective study included patients diagnosed with Stage III-IV NSCLC between 2016 and 2021. The primary outcome was receipt of immunotherapy. Trends were evaluated by diagnosis year. We fit multivariable logistic regression models to assess demographic, socioeconomic, and facility-level factors associated with immunotherapy use.

Results: Of 130,328 NSCLC patients, immunotherapy use rose from 10% in 2016 to 41% in 2021. The largest increase occurred between 2016 and 2019, aligning with major clinical trial results and guideline changes. However, only 41% of patients received immunotherapy in 2021, raising concerns about adoption barriers extending beyond clinical contraindications or biomarker exclusions. In multivariable analysis, patients treated at academic centers had higher odds of immunotherapy receipt (OR: 1.07, 95% CI: 1.06-1.09). Compared to non-Hispanic White patients, the odds of immunotherapy receipt were lower among Black (OR: 0.92, 95% CI: 0.90-0.94), Hispanic (OR: 0.76, 95% CI: 0.73-0.79), and Asian/Pacific Islander (OR: 0.67, 95% CI: 0.65-0.70) patients. Privately insured patients had greater odds of immunotherapy receipt than Medicaid enrollees (OR: 1.16, 95% CI: 1.13-1.20), while the odds were lower for Medicare enrollees (OR: 0.86, 95% CI: 0.84-0.88) or those uninsured (OR: 0.76, 95% CI: 0.72-0.80). Higher-income quartiles were associated with greater odds of immunotherapy use (OR: 1.03, 95% CI: 1.00-1.06); areas with higher high school non-completion rates had reduced odds (OR: 0.82, 95% CI: 0.79-0.84). Compared to metro residence, rural (OR: 1.10, 95% CI: 1.05-1.16) or urban (OR: 1.04, 95% CI: 1.02-1.06) residence was associated with greater odds of immunotherapy use. Female patients had lower odds of receiving immunotherapy than males (OR: 0.95, 95% CI: 0.94-0.97).

Conclusions: In this large national cohort of Stage III-IV NSCLC patients, immunotherapy utilization increased substantially between 2016 and 2021. However, real-world delivery continues to lag behind clinical expectations, with fewer than half of patients receiving recommended ICIs in recent years. Uptake varied across socioeconomic and demographic factors, underscoring the need for targeted efforts to close treatment gaps and ensure equitable access to immunotherapy in lung cancer care.

Table. Rates of Immunotherapy Use and Associated Characteristics in Patients with Stage III-IV NSCLC

Year	Immunotherapy Use, N (%)	OR (95% CI), p	Characteristic	Comparison	OR (95% CI), p
2016	7,647 (10%)	Reference year	**Facility Type**	Academic vs. Non-Academic (ref.)	1.07 (1.06–1.09), p<0.001
2017	15,697 (21%)	2.32 (2.25–2.39), p<0.001	**Race/Ethnicity**	Black vs. White (ref.)	0.92 (0.90–0.94), p<0.001
				Hispanic vs. White	0.76 (0.73–0.79), p<0.001
				Asian/Pacific Islander vs. White	0.67 (0.65–0.70), p<0.001
2018	24,163 (34%)	4.59 (4.46–4.72), p<0.001	**Insurance Type**	Private vs. Medicaid (ref.)	1.16 (1.13–1.20), p<0.001
				Medicare vs. Medicaid	0.86 (0.84–0.88), p<0.001
				Not Insured vs. Medicaid	0.76 (0.72–0.80), p<0.001
				Other Government vs. Medicaid	0.82 (0.78–0.87), p<0.001
2019	28,854 (40%)	6.08 (5.91–6.25), p<0.001	**Median Household Income Quartiles**	≥$74,063 vs. ≤$46,277 (ref.)	1.03 (1.00–1.06), p=0.046
2020	26,465 (41%)	6.34 (6.16–6.52), p<0.001	**Percent High School Non-Completion**	≥15.3% vs. <5% non-completion (ref.)	0.82 (0.79–0.84), p<0.001
2021	27,502 (41%)	6.53 (6.34–6.71), p<0.001	**Location**	Rural vs. Metro (ref.)	1.10 (1.05–1.16), p<0.001
				Urban vs. Metro	1.04 (1.02–1.06), p<0.001
			Sex	Female vs. Male (ref.)	0.95 (0.94–0.97), p<0.001

P1.17.60 Characterizing Multi-Timepoint Lung Cancer Progression With Dynamic Bayesian Network, Structural Equation Modeling and Random Forest Model

W. Liu, J.C.S. CHAN, A.T.C. Chang, J.W.Y. CHAN, R.W.H. Lau, C.S.H. Ng
Prince of Wales Hospital, The Chinese University of Hong Kong, Hongkong/CN

Introduction: Although significant advances have been made in lung cancer treatment, post-treatment disease progression including intrapulmonary metastasis (IPM), multiple primary lung cancer (MPLC), and single primary lung cancer (SPLC), remains common. This study aims to investigate how clinical and sociodemographic factors influence lung cancer progression and to evaluate the effects of different surgical and systemic treatment approaches on subsequent disease outcomes.

Methods: Lung cancer patients with at least two recorded visits in SEER (2000-2019) were included. Dynamic Bayesian networks (DBNs) identified key temporal relationships among baseline (t0), first (t1), second (t2), and third (t3) diagnoses. A simulated intervention (SI) was performed by fixing the DBN structure and modifying surgical/systemic therapy scenarios to calculate hazard ratios (HRs) for IPM, MPLC, and SPLC. Structural equation modeling (SEM) and random forest were used to validate the DBN findings.

Results: Of the 3,450 patients, 337 experienced IPM, 24 had MPLC, and 3,089 had SPLC as their first lung cancer progression. Baseline analysis revealed significant group differences in TNM stage, treatment details, grade, and pathology. The DBN highlighted T_Stage_t2, Surgery_t1, Age_Phase_t1/t2, and TNM_Stage_t1/t2 as key factors for first disease progression. Segmentectomy did not significantly alter progression risk relative to lobectomy with mediastinal lymph node dissection (MLND) or wedge resection ($p > 0.05$). Compared to wedge resection, lobectomy with MLND lowered IPM risk while increasing SPLC risk in disease progression [HR of IPM: 0.7513 (95% CI: 0.6176-0.8988); HR of SPLC: 1.0299 (95% CI: 1.0101-1.0530)]. In stage I patients, lobectomy reduced MPLC risk compared to no surgery in disease progression [Stage IA+IB: 0.4781 (95% CI: 0.2257-0.8098)], though this was not observed in stage II or later ($p > 0.05$). Chemotherapy and radiotherapy also influenced progression, increasing the risk of IPM compared with none-chemotherapy and none-radiotherapy group [Chemotherapy: 1.2681 (95% CI: 1.1908-1.3503); beam radiation: 1.3850 (95% CI: 1.2440-1.5480)] and MPLC [Chemotherapy: 1.1741 (95% CI: 1.0676-1.3029); beam radiation: 1.2617 (95% CI: 1.1026-1.4550)] while decreasing SPLC risk [Chemotherapy: 0.9692 (95% CI: 0.9602-0.9773); beam radiation: 0.9582 (95% CI: 0.9408-0.9728)]. SEM validated core pathways, and random forest identified Surgery_t1_Not received and T_Stage_t2 as key predictors for first disease progression.

Conclusions: This study emphasizes the role of surgery, tumor staging, systemic therapy, and their timing in lung cancer progression. By leveraging multi-timepoint data and advanced modeling, we can explore strategies to mitigate high-risk progression events, such as IPM and MPLC, thereby supporting stage-specific personalized treatment approaches to optimize patient outcomes.

P1.17.61 Rebiopsy in Oncogene-Driven Lung Cancer: Real-World Practices in ALK, EGFR, and ROS1 Cohorts in the Australian AURORA Longitudinal Cohort Study

S. Harden[1,2], A. Nguyen[3], L. Rashed[3], F. Tadesse[3], A. Truong[3], H. Zhang[3], J. Rogers[1], L. Selbie[1], D. Arasaratnam[1], J. Geng[1], C. Williams[1], L. Tan[1,2], T. Spelman[1,2], B. Solomon[1,2], M. Alexander[1,2]
[1]Peter MacCallum Cancer Centre, Melbourne/AU ,[2]The University of Melbourne, Melbourne/AU ,[3]Monash University, Melbourne/AU

Introduction: Targetable mutations including EGFR, ALK, and ROS1 have expanded advanced NSCLC treatment options. However, identifying genomic drivers of progression remains challenging, with re-biopsies crucial for detecting resistance mechanisms and guiding therapy. Real-world practice is unclear. We examined re-biopsy patterns in EGFR, ALK, and ROS1 NSCLC at an Australian cancer centre using data from the AUstralasian thoRacic cancers lOngitudinal cohoRt study and biobAnk (AURORA, ACTRN12625000038493).

Methods: This retrospective real-world study used AURORA data from Peter MacCallum Cancer Centre. Eligible patients were enrolled before 14Feb2025, with diagnosis of EGFR, ALK, or ROS1 NSCLC. Focussed on current treatments within a manageable cohort size, EGFR was limited to patients receiving first-line osimertinib. No treatment-based eligibility was applied to ALK/ROS1 cohorts. All biopsy types were included, noting liquid biopsies were unfunded and accessed through trials. Biopsy characteristics (sample type, frequency, and context—diagnostic, resection, on-treatment, progression, or surveillance) were analysed over time. Treatment lines and local therapies were reported to contextualise re-biopsy patterns. Data were extracted from AURORA, updated via medical record review, and analysed using descriptive statistics and visualised by Swimmer plot.

Results: This analysis included 622 biopsies from 281 patients: 141 ALK+, 105 EGFR+, and 35 ROS1+. The median biopsies per patient was 2 (range 1-9). All had a diagnostic biopsy (326 total), with 28% at resection (95 biopsies), 12% on-treatment (47 biopsies), 56% at progression (144 biopsies), and 2% for surveillance (10 biopsies). Most were tissue biopsies (N=388, 62%), with fewer cytology samples (N=224, 36%) and limited liquid biopsies (N=10, 2%). Re-biopsy at progression increased over time from 51% to 70%, p=0.04 (Figure 1). Among EGFR+ first-line osimertinib patients, 16% (17/105) had prior early-stage treatment. In subsequent lines, 23% (24/105) received EGFR-targeted therapies, including 19% (20/105) rechallenged with osimertinib, 22% (24/105) received chemotherapy, and 56% (59/105) radiotherapy. Among ALK+ patients, the most common first-line treatments were alectinib (26%, 37/141), crizotinib (24%, 34/141), chemotherapy (20%, 29/141), and lorlatinib (12%, 17/141). Across all lines, 38% (54/141) received ALK-targeted therapies, and 60% (84/141) radiotherapy. Among ROS1+ patients, first-line treatments included entrectinib (23%, 8/35), crizotinib (23%, 8/35), and chemotherapy (20%, 7/35). Across all lines, 80% (28/35) received ROS1-targeted therapies, and 51% (18/35) radiotherapy.

Conclusions: Treatment selection and sequences reflect new evidence and drug availability over the reporting period. Re-biopsy at progression increased over time with evolving evidence of benefit, increasing opportunities for personalised treatment selection. Improved access to funded liquid re-biopsy may further improve rates.

Introduction: ROS1-rearranged non-small cell lung cancer (ROS1 NSCLC) is a rare, yet clinically significant subset driven by oncogenic ROS1 fusions. While targeted therapies have transformed outcomes, real-world data on treatment patterns and survival remain limited. This consumer-informed analysis leverages the AUstralasian thoRacic cancers lOngitudinal cohoRt study and biobAnk (AURORA) to present one of the largest real-world ROS1 NSCLC cohorts, providing a comprehensive evaluation of patient characteristics, treatment approaches, and survival across multiple Australian hospitals.

Methods: Patients with ROS1 NSCLC diagnosed by fluorescence in situ hybridization (FISH) or next-generation sequencing (NGS) enrolled in AURORA (ACTRN12625000038493) were included. Key outcomes included demographics, diagnostics, treatment patterns, and overall survival (OS). OS was estimated using Kaplan-Meier analysis and measured from ROS1 NSCLC diagnosis. The cohort continues to enrol as part of ongoing AURORA enrolment, with a final data cut on this analysis in June 2025 to enable multivariate modelling on clinical and molecular markers of treatment performance. This study is supported by the Kha Kiang Khoo Memorial Award, Lung Foundation Australia.

Results: Among 104 patients enrolled across 15 hospitals with ROS1 NSCLC diagnosed 2009-2024, median age was 56 years (range: 24-79), and 66% (69/104) were female. At diagnosis, 24% (24/104) had early-stage disease treated with curative intent, while 76% (80/104) presented with advanced/metastatic disease, including 14% (11/80) with brain metastases. Among early-stage patients, 54% (13/24) subsequently relapsed and received treatment for advanced disease. In the advanced treatment setting (93/104, 89%), the median number of treatment lines was 2 (range: 1-8). Most received one (32/93, 34%) or two (29/93, 31%) therapy lines, while 34% (32/93) underwent three-lines or more, including one patient with eight lines. ROS1-directed therapy was given first-line in 72% (67/93) and at any line in 96% (89/93), accounting for total 239 lines of ROS-1 therapies. Entrectinib (31/93, 33%) and crizotinib (23/93, 25%) were the most common first-line targeted agents. Across all lines, entrectinib (35/93, 38%) and crizotinib (33/93, 35%) were frequently used, followed by lorlatinib (26/93, 28%), NVL-520 (24/93, 26%), repotrectinib (17/93, 18%). Clinical trial enrolment was 17% (16/93) at first line and 59% (55/93) overall. Median OS was 92 months (95%CI: 54-NR) in early-stage patients treated with curative intent (N=24). For those diagnosed with de-novo advanced/metastatic disease (N=80), median OS was 56 months (95%CI: 49-82). In the subgroup receiving first-line ROS1-directed therapy in the advanced disease setting (N=67), median OS was 56 months (95%CI: 49-92).

Conclusions: In this large real-world ROS1 NSCLC cohort, 72% received ROS1-directed therapy in the first line, and 96% at any line, with 59% enrolled in trials. First-line ROS1 therapy demonstrated a median survival of 56 months, comparable to PROFILE 1001 (51 months) and exceeding other real-world cohorts (24 months), likely due to reflex molecular testing, targeted therapy access, and trial prioritisation. This real-world data provides valuable insights into the longitudinal patient journey, outcomes with serial therapies, and the potential impact of treatment sequencing.

P1.17.63 Docetaxel and Docetaxel Plus Ramucirumab Demonstrate Similar Real-World Overall Survival: A Contemporary Analysis

L-I. Hsu[1], R. Gennarelli[2], Z. Zhou[3], C. Gutierrez[3], J. Smith[4], S. Knowles[4], A. Hohlbauch[3]
[1]Pfizer, South San Francisco/CA/USA ,[2]Cencora, Conshohocken/PA/USA ,[3]Genesis Research Group, Hoboken/NJ/USA ,[4]Pfizer, Bothell/WA/USA

Introduction: In the US, docetaxel as a monotherapy or in combination with ramucirumab are standard treatment options for patients with NSCLC following disease progression on or after immunotherapy (IO) with or without platinum-based chemotherapy (PBC). In clinical trials, median overall survival (OS) was 9.1-12.5 months with docetaxel and 10.5 months with docetaxel plus ramucirumab. This study describes real-world clinical outcomes in patients with NSCLC who received docetaxel monotherapy or combined with ramucirumab following PBC and IO.

Methods: This retrospective study included patients from the nationwide Flatiron Health electronic health record-derived deidentified database who had advanced NSCLC and were treated with PBC and IO separately or in combination, followed by second-line or later docetaxel or docetaxel plus ramucirumab between January 1, 2011, and August 31, 2022. Real-world OS (rwOS) and real-world progression-free survival (rwPFS) were examined from docetaxel-containing therapy initiation to end of follow-up (February 28, 2023).

Results: Of the 1696 patients who received docetaxel or docetaxel plus ramucirumab, 1295 (76%) had nonsquamous histology, and 484 (29%) had an actionable genomic alteration (AGA). Median rwOS was 6.7 months (95% CI, 6.2-7.2) in the overall population; rwOS was similar with docetaxel (6.3 months [95% CI, 5.8-7.4]) and docetaxel plus ramucirumab (6.9 months [95% CI, 6.2-7.4]), regardless of histology or AGA status (Table). In the subgroup of patients with nonsquamous NSCLC and no prior taxane use, median rwOS was 7.3 months (95% CI, 6.6-7.8) and similar with docetaxel and docetaxel plus ramucirumab regimens. Median rwPFS was 3.5 months (95% CI, 3.2-3.7) in the overall population but shorter with docetaxel (2.8 months) vs docetaxel plus ramucirumab (3.9 months); median rwPFS outcomes were similar across histological subtypes and in the nonsquamous and no prior taxane subgroup.

Conclusions: For patients with advanced NSCLC receiving docetaxel or docetaxel plus ramucirumab in the second-line setting or later, rwOS is poor at approximately 6.7 months and similar with either regimen. Current treatment options are inadequate and there is a pressing need for novel therapies to improve patient outcomes.

P1.17.64 Acinar Cell Lung Carcinoma: A Unique Subtype of NSCLC Adenocarcinoma,Insights From the AACR Project Genie Database

A.M. Zayed[1], Y. Hamadneh[2], O. Younis[2], H. Abu jazar[1], A. Yasin[1], M. Zayed[3], K. Al-Rabi[1]
[1]king hussein cancer center, Amman/JO ,[2]Jordan University, Amman/JO ,[3]Jordan University of Science and Technology JUST, Irbid/JO

Introduction: Acinar cell lung carcinoma (ACLC) is a rare subtype of non-small cell lung cancer (NSCLC), accounting for approximately 6.0% of cases. ACLC exhibits unique clinical and genetic characteristics compared to other NSCLC adenocarcinoma subtypes. This study utilizes data from cBioPortal and GENIE to evaluate and compare the molecular, clinical, and survival profiles of ACLC and adenocarcinoma lung cancer Not Otherwise Specified(NOS)

Methods: This retrospective cohort study analyzed 798 patients, including 109 with ACLC and 689 with adenocarcinoma not otherwise specified (NOS). Genetic mutation profiles, clinical characteristics (age, gender, stage, race, and organ involvement in stage IV disease), and overall survival (OS) in stage IV were compared. Statistical tests included chi-square for categorical variables and Kaplan-Meier survival curves with Cox proportional hazards modeling for OS analysis.

Results: The median age at diagnosis was significantly higher in ACLC (69.2 years) than in adenocarcinoma NOS (65.4 years; p = 0.002). Both groups were predominantly White (ACLC: 86.2%, adenocarcinoma NOS 79.6%) with no significant racial differences (p = 0.18). Females were more frequently diagnosed with ACLC (79.1%) compared to adenocarcinoma NOS (57.4%; p < 0.0002). ACLC was more often diagnosed at earlier stages (Stage I: 50% vs. 13%) and less frequently at Stage IV (28% vs. 72%; p < 0.0001). In stage IV, the organ involvement was similar between the groups. Median OS in Stage IV ACLC was 23.1 months (95% CI: 14.8-NA) versus 27.6 months in adenocarcinoma NOS (95% CI: 23.6-29.7; p = 0.5) Genetic analysis showed TP53 mutations were significantly less frequent in ACLC (43.33%) compared to adenocarcinoma NOS (56.5%; p = 0.007), while KRAS mutations were more common in ACLC (36.67% vs. 31.8%; p = 0.2). Among targetable mutations, EGFR (25.83% vs. 29.8%; p = 0.39), ALK (8.33% vs. 9.5%; p = 0.8), and ROS1 mutations were absent in ACLC but present in 5.51% of adenocarcinoma NOS (p = 0.006); RET (7.50% vs. 4.5%; p = 0.1), MET (10.83% vs. 7%; p = 0.19), NTRK1 (0.88% vs. 3.90%; p = 0.18), and BRAF (4.17% vs. 5.9%; p = 0.53) mutations were less common in ACLC.

Conclusions: Acinar cell lung cancer differs from lung adenocarcinoma NOS in several important aspects. Patients with ACLC are typically older, more often female, and diagnosed in earlier stages with similar survival in stage IV. It also has a distinct genetic pattern since ACLC has a lower incidence of TP53 and ROS1 with a comparable rate of other targetable mutations, so this suggests a unique subtype that needs further precise treatment.

P1.17.65 Age-Associated Incidence of Somatic Mutations and Survival Outcomes in Non-Small Cell Lung Cancer

S. Sertich[1], N. Gandhi[2], A. Pruitt[1], J. Kusiel[1], A. Elliott[2], A. Vanderwalde[2], R. Hsu[3], B. Halmos[4], S. Arnold[1], J. Villano[1], R. Zinner[1], Z. Hao[1]
[1]University of Kentucky, Lexington/KY/USA ,[2]Caris Life Sciences, Phoenix/AZ/USA ,[3]Keck School of Medicine of USC, San Diego/CA/USA ,[4]Montefiore Einstein Comprehensive Cancer Center, Bronx/NY/USA

Introduction: In NSCLC, the incidence of driver mutations and their prognostic role related to age are poorly described, especially for young and longevous adults. This study aims to describe the molecular landscape and survival of patients of different ages with NSCLC.

Methods: 40,510 NSCLC specimens underwent DNA/RNA sequencing at Caris Life Sciences. Patients were stratified based on age at specimen collection into adolescent/young adults (AYA, <40 years, 0.6%), older adults (OA, 40-65 years, 37%), geriatric adults (GA, 66-79 years, 49%), and longevous adults (LA, 80+ years, 14%). Survival was calculated from claims data using Kaplan-Meier estimates with overall survival (OS) from sample collection to last contact. Multiple hypothesis corrections were made where applicable with q<.05 denoting significance.

Results: Sex did not differ between groups. Fewer AYA smoked or were Caucasian; Black race was less common with advancing age (q<.05; Table 1). Mutations in many tumor suppressor genes (TSG) were least common in AYA, peaked in OA, then declined in GA/LA (for example, TP53 mutation incidence was 52% in AYA, 71% OA, 66% GA, 60% LA; q<.05). The incidence of individual TSG mutations did not differ between AYA and LA except GNAS and NF1. GNAS was the only TSG that had highest incidence in AYA (3.1% vs 0.49% - 0.68% OA/GA/LA, q<.05). While the overall incidence of driver mutation was highest among AYA (67% vs 49-54%, q<0.05), specific alterations such as METex14 skipping and KRAS mutations (mimicking smoking history) were more prevalent among older age groups (q<.05; Table 1). EGFR mutations were equally incident across age; however, AYA had less frequent L858R (0% vs 17-33%) and more frequent Del19 (67% vs 33-41%, q<.05) mutations. OS declined with advancing age for driver-negative, BRAF+, and KRAS+ tumors. However, AYA OS was heterogeneous between driver groups, with longer OS (compared to LA) in ALK+ and driver-negative tumors but no differences in ERBB2 and EGFR mutations (Table 1). Interestingly, OA with Del19 had longer OS compared to OA with L858R (p<.05); this was not noted in other age groups.

Conclusions: AYA patients with NSCLC had more driver mutations and fewer TSG and RAS-pathway mutations than older patients. GNAS mutations have not previously been known to be associated with younger age. While increasing age is generally associated with shorter OS, there were substantial deviations from this trend, most notable in EGFR mutations.

Table 1: Demographics, driver mutation incidence, and overall survival by age cohort

		AYA (18-39 years)	OA (40-65 years)	GA (66-79 years)	LA (80+ years)
N		259	15014	19361	5606
Female sex		52.1%	49.6%	49.6%	49.5%

P1.17.66 Impact of Concurrent Tissue and Liquid Comprehensive Genomic Profiling (CGP) on Receipt of First-Line (1L) Therapy in a NSCLC

J.W. Riess[1], J.K. Lee[2], G. Li[2], R. Graf[2], A. Gasco[2], A.B. Schrock[2], R.S. Huang[2]
[1]UC Davis Comprehensive Cancer Center, Sacramento/CA/USA ,[2]Foundation Medicine, Inc., Boston/MA/USA

Introduction: With the growing array of targeted treatments for patients with advanced NSCLC (aNSCLC), molecular testing to inform 1L therapy selection has become a guideline-recommended practice. Liquid biopsy offers a pragmatic, non-invasive alternative with a faster turnaround time. We sought to examine the effect of concurrent tissue-liquid testing on 1L therapy selection and outcomes.

Methods: The US-based de-identified Flatiron Health-Foundation Medicine (FMI) clinico-genomic database (CGDB) was queried to assess the patterns of 1L biomarker testing (FMI and abstracted non-FMI central lab CGP providers) for NCCN-defined drivers for 3,005 patients diagnosed with denovo aNSCLC between 9/2020-9/2024 with ≥1 CGP test reported before 1L treatment. Tissue and liquid tests were classified as concurrent when both were ordered before the report date of either test, sequential if the first test was ordered before 1L and the second was ordered 1-60 days after the first report, and single testing if one test result reported before 1L and no second test was ordered within 60 days. Outcomes were summarized by real-world overall survival [rwOS], progression-free survival [rwPFS)], and time-to-next-treatment [rwTTNT] for the EGFR+ subset, a longstanding and well-defined actionable driver.

Results: Of 3,005 aNSCLC patients with a tissue or liquid CGP test reported before 1L therapy initiation, 565 (19%) had concurrently ordered tissue-liquid tests, 289 (10%) had sequentially ordered tests (73% liquid-first), 1,274 (42%) had tissue-only, and 877 (29%) had liquid-only testing. There were no significant differences in age, sex, practice type, socioeconomic status, or ECOG PS between cohorts. Concurrent testing was more likely to result in a driver+ report than sequential, tissue-only, and liquid-only testing (65% vs. 59% vs. 53% vs. 48%, p<0.01) and had the highest rate of 1L targeted therapy receipt (24% vs. 16-21%, p<0.01). Concurrent testing was also associated with a shorter time from the first CGP order to 1L treatment than sequential (24 vs. 28 days, p=0.009) and tissue-only testing (24 vs. 30 days, p<0.001) but was not significantly different from patients with liquid-only testing (24 vs. 23 days, p=0.20). Among driver+ patients, 76% of patients with concurrent testing started 1L therapy after receipt of both tissue and liquid reports vs. 37% of liquid-first sequential testing patients (p<0.01). Among EGFR+ patients, 1L-matched targeted therapy was initiated for 80% of concurrent (median 23 days post-first order) and 74% of liquid-first sequential (27 days post-first order) testing patients. In these patients, we observed longer rwOS (26 vs. 18 mos; HR 0.52; 95% CI 0.31-0.90; p=0.02), rwPFS (11 vs. 6.7 mos; HR 0.75; 95% CI 0.48-1.19; p=0.23), and rwTTNT (13 vs. 8.0 mos; HR 0.64; 95% CI 0.41-1.01; p=0.06) in patients with concurrent vs. liquid-first sequential testing.

Conclusions: In this large CGDB, patients with tissue and liquid CGP ordered concurrently or sequentially, higher rates of driver detection than those with a single test were observed. Patients with tissue and liquid CGP ordered concurrently also had a faster time to 1L start than sequential testing. Among EGFR+ patients, those with concurrent testing had superior outcomes than those with liquid followed by tissue CGP.

Introduction: Immune checkpoint inhibitors (ICIs) have improved outcomes in clinical trials for metastatic non-small cell lung cancer (mNSCLC). However, evidence of the uptake, treatment, and effectiveness patterns of ICIs in real-world settings, particularly across diverse healthcare systems and populations, remains scarce. Real-world data (RWD) is vital to complement clinical trial findings. Yet, barriers such as data standardization, lack of networks, especially across borders, and privacy concerns hinder comprehensive global assessments.

Data harmonization to the OMOP common data model (CDM) and federated data analysis frameworks address these challenges by enabling standardized, large-scale analyses while maintaining patient privacy.In March 2025, a mNSCLC study-a-thon held in Helsinki brought together a multidisciplinary team from 21 sites and nine countries, from academic and industry data partners, with the primary objective to characterize patients with mNSCLC and evaluate shifts in treatment patterns and outcomes after introduction of ICIs.

Methods: This study-a-thon introduced an iterative, standardized data readiness and quality workflow for oncology studies. Each participating Data Partner executed a comprehensive lung cancer-specific Data Quality Assessment, followed by a corrective patching script executed individually on the OMOP database at each site, to ensure data interoperability and quality. The study cohorts included adult patients with NSCLC and no other cancer, diagnosed after January 1st 2015. Specific cohorts included patients with NSCLC and mNSCLC, as well as the subset that initiated standard-of-care systemic therapies for metastatic disease. mNSCLC regimens in each database were inferred from individual drug prescriptions using the open-source OHDSI ARTEMIS package. Key outcomes were overall survival, time to subsequent treatment, time to treatment discontinuation, and treatment-free interval.

Results: Fifty data partners completed the oncology data readiness assessment and 22 qualified for inclusion in a mNSCLC study-a-thon. Currently, 17 data partners are actively running the study package and results from 11 are available now. So far, 25,352 patients with NSCLC from Australia, Belgium, Finland, Germany, Spain, the UK, and the US are included in the study. Median age ranges from 65 years in the Roche WAYFIND-R (Basel) database to 72 years in Tampere University Hospital (Finland). The proportion of men ranges from 43% in DFCI (Boston) to 69% in IIS La Fe (Valencia). Median follow-up time in the NSCLC cohort is between 306 days in Wayfind-R and 642 days in Emory University (Atlanta). Detailed analysis for the different cohorts is ongoing and will be presented at the Conference.

Conclusions: Our experience from the iCAN mNSCLC study-a-thon demonstrates that high-quality, secure, reproducible, and scalable lung cancer RWE research is achievable and essential, setting the stage for future efforts.Given the complexity, specificity, and granularity required in oncology data, such as detailed histology and treatment episode abstraction, individual data sources rarely suffice to achieve robust sample sizes for meaningful inference. Standardized community-developed and -maintained methods, tools, and systematic quality assurance practices are critical to managing this complexity. Furthermore, intensive and structured collaborations, exemplified by the study-a-thon model, enable rapid iterative improvements and sustained engagement across multiple data partners.

P1.17.68 Real-World Validation of Other Disease Morbidity After Lung Cancer Surgery Using a Japanese Database in Reference to JCOG0802/WJOG4607L

T. Taihei[1], T. Yoshioka[1], K. Yagi[2], S. Matsui[1], A. Baba[1], E. Takehara[1], K. Fujimoto[1], N. Miyamoto[1], A. Morishita[1], N. Kawakita[1], H. Toba[1], K. Ishizawa[1], H. Takizawa[1]
[1]Tokushima University, Tokushima City/JP ,[2]Shimane University Hospital, Shimane/JP

Introduction: The JCOG0802/WJOG4607L phase III trial demonstrated that segmentectomy was superior to lobectomy in terms of overall survival (OS) for peripheral small non-small cell lung cancer. The difference in OS was attributed not to lung cancer-related deaths but rather to other causes, such as other cancers, respiratory diseases, and cerebrovascular diseases. The direct impact of surgery on morbidity of other diseases remains unclear. Postoperative morbidity from other diseases and subsequent hospitalizations may contribute to reduced activities of daily living (ADL) and shortened OS. Since studies comprehensively assessing the risk of non-cancer-related mortality and morbidity after lung cancer surgery are scarce, we utilized the JMDC database to analyze OS based on readmission rates due to other diseases after pneumonectomy.

Methods: JMDC, Inc. has created a database using data collected from health insurance societies in Japan, consisting of claims (including hospitalization, outpatient treatment and drug prescriptions), and health checkup results. Using the JMDC Receipt Database, We analyzed 3,349 cases of thoracoscopic lobectomy (lobectomy group) and 744 cases of thoracoscopic lung segmentectomy (segmentectomy group) for lung cancer between 2011 and 2021. Postoperative readmissions were classified based on ICD-10 criteria for the following conditions: pneumonia, congestive heart failure, ischemic heart disease, cerebral infarction, cerebral hemorrhage, arrhythmia, aortic dissection, valvular heart disease, and sudden death. Pneumonia-related readmissions were identified based on antibiotic use. Health checkup data, number of readmissions, and disease-specific overall survival (OS) were analyzed by surgical procedure.

Results: The patient cohort (n=4093) had a median age of 57 years, with approximately 60% being male. The median observation period was approximately two years. Pneumonia was the most frequent cause of rehospitalization (6.8%), followed by heart failure (3.5%), ischemic heart disease (3.2%), and stroke (1.6%). Although significant differences were observed in age, gender, observation period, and smoking history between the lobectomy and segmentectomy groups, no significant differences were found in health checkup data. Postoperative readmissions varied significantly by procedure: pneumonia (lobectomy: 7.4% vs. segmentectomy: 4.6%, $p<0.005$), heart failure (lobectomy: 4.0% vs. segmentectomy: 2.4%, $p=0.039$), and cerebral infarction (lobectomy: 1.9% vs. segmentectomy: 0.5%, $p=0.007$). The cumulative readmission rate was higher in the lobectomy group for pneumonia ($p=0.012$) and cerebral infarction ($p=0.0112$). The five-year OS analysis showed that rehospitalization for pneumonia, cerebral infarction, cerebral hemorrhage, aortic dissection, and sudden death was associated with worse OS regardless of the procedure ($p<0.001$ for all these conditions). Additionally, OS was significantly worse in the lobectomy group for heart failure ($p<0.001$), ischemic heart disease ($p=0.022$), and arrhythmia ($p=0.04$).

Conclusions: This study revealed that specific diseases had higher rehospitalization rates depending on the surgical procedure. Lung preservation through segmentectomy may have contributed to maintaining cardiopulmonary function, potentially preventing the progression of pneumonia and heart failure to a severity requiring hospitalization. Maintaining performance status (PS) after surgery is fundamental in cancer treatment. Our findings suggest that non-cancer disease-related hospitalizations may contribute to PS decline, ultimately impacting OS. Given that our study population was relatively young, the effect of hospitalizations on OS might be less pronounced than in an older population.

Introduction: To evaluate the impact of telehealth care on the efficacy and safety of patients with advanced ALK-fusion NSCLC undergoing first line ALK-TKI therapy.

Methods: Treatment-naïve ALK fusion-positive advanced NSCLC patients receiving first-line ALK-TKI therapy were enrolled in the WeDoc telehealth care system. Patient-physician communication regarding treatment and adverse events was facilitated via the WeDoc online platform. Progression-free survival (PFS) and adverse events (AEs) were compared among patients treated with different ALK-TKIs, including alectinib, brigatinib, and lorlatinib. Multivariate regression analysis was performed to identify factors influencing PFS and AE, including clinical and molecular characteristics, communication frequency, and adherence to telehealth care protocols.

Results: From June 2021 to September 2024, 174 advanced NSCLC patients treated with ALK-TKIs were enrolled in the WeDoc telehealth system across 15 Chinese hospitals. The cohort comprised 102 patients in the alectinib group, 40 in the brigatinib group, and 32 in the lorlatinib group. The objective response rates (ORRs) were 80.3%, 80%, and 78.9%, respectively. Median progression-free survival (PFS) was 31 months (30.9-NR) for alectinib, while PFS for brigatinib (14.4-NR) and lorlatinib (10.0-NR) remained unreached due to insufficient follow-up time. No significant differences in ORR or PFS were observed among the three groups. Multivariate regression analysis in the alectinib group identified adherence to WeDoc telehealth protocols and close doctor-patient communication as independent factors associated with prolonged PFS, without significant impact on side effects or patient-reported outcomes.

Conclusions: The use of WeDoc, a telehealth system, for managing advanced NSCLC patients on long-term ALK-TKI therapy in real-world practice is linked to prolonged PFS, warranting validation through future randomized controlled trials.

Variable	N	Multivariate analysis
		HR

P1.17.70 Clinicomolecular Characteristics and Treatment Patterns in Stage IV NSCLC: A Retrospective Study From Southwestern Ontario

J. Moroniti[1], S. Surapaneni[2,3], S. Ma[1,3], A. Carolina da Cruz[4], M. Qiabi[1,2,3], M. Vincent[1,2,3], M. Sanatani[1,2,3], J. Younus[1,2,3], D. Breadner[1,2,3], P. Blanchette[1,2,3], H. Mithoowani[1,2,3], D. Logan[1,2,3], J. Raphael[1,2,3], R. Sachdeva[5], M.S. Kuruvilla[1,2,3]
[1]Schulich School of Medicine and Dentistry, London/ON/CA ,[2]Department of Oncology, Verspeeten Family Cancer Centre, London Health Sciences Center, London/ON/CA ,[3]London Health Sciences Centre Research Institute, London/ON/CA ,[4]Department of Statistical and Actuarial Sciences, Western University, London/ON/CA ,[5]Precision Medicine Group, LLC, London/ON/CA

Introduction: Non-small cell lung cancer (NSCLC) is a leading cause of cancer-related mortality in Canada, with over half of patients diagnosed with advanced disease. Outcomes for Stage IV disease remain poor, with a 5-year survival rate of <10%. Recent advancements in treatment, particularly immunotherapies, hold promise for improving clinical outcomes. However, the real-world implementation and impact of these treatments remain uncertain. This is especially true for Southwestern Ontario, Canada, a region with a large, demographically diverse population and varying levels of healthcare access. Our study aims to evaluate emerging clinico-pathologic characteristics, treatment patterns, and clinical outcomes of this population in a real-world setting.

Methods: We conducted a retrospective chart review of serially registered adult patients diagnosed with Stage IV NSCLC at the London Health Sciences Centre, Ontario, Canada, between January 1, 2017, and December 31, 2020. Data on demographics, clinico-pathologic features, treatment characteristics, toxicity, progression, and survival were collected. Descriptive statistics were applied to demographic, treatment and clinico-pathologic characteristics. The data cutoff was May 4, 2024. The research protocol was approved by the local research ethics board.

Results: A total of 523 patients were included in the analysis. Median age was 69 years, approximately 50% male, and >85% current or former smokers. Adenocarcinoma was the most common histologic subtype (~70%). Autoimmune comorbidities present in <5% of patients. ALK mutations were identified in <3% of patients, while EGFR mutations in approximately 11%. Of those with known PD-L1 status, PD-L1 expression was negative in 30.4%, weakly positive in 31.2%, and strongly positive in 38.4%. PD-L1 status was unknown in 23.9% of patients. Of patients who received first-line systemic treatment, 31.2% received single-agent immunotherapy, 17.2% chemoimmunotherapy, 33.2% chemotherapy, and 18.4% molecularly targeted therapies. Of the entire cohort, 31.7% patients received palliative radiation alone, and 11.3% received no treatment. PD-L1 status was associated with treatment selection (Figure 1).

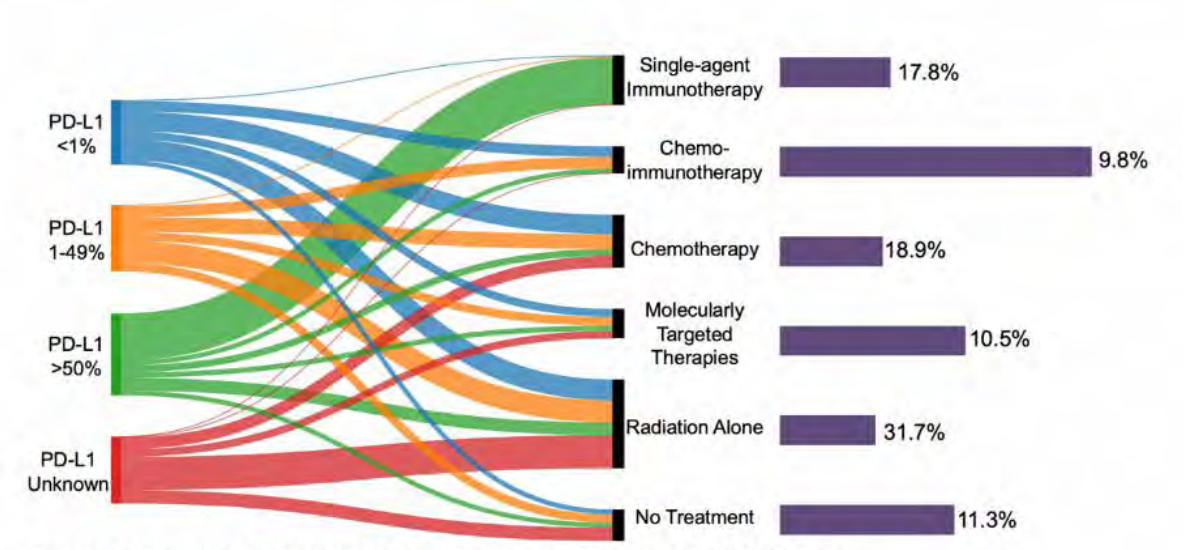

Figure 1: First-line treatment by PD-L1 status in Stage IV NSCLC

Conclusions: Lung cancer patients in Southwestern Ontario represent a distinct population. The prevalence of EGFR and ALK mutations mirrors rates seen in early-stage NSCLC in this region. Despite a high smoking rate (>85%), squamous cell carcinoma accounted for a small minority of patients. First-line treatment was influenced by PD-L1 status, reflecting knowledge translation efforts. Notably, about 40% of patients received palliative radiotherapy or no treatment, highlighting a significant segment of patients not being able to access available systemic therapy. Limitations include missing data and potential regional bias. Future research will assess clinical outcomes in this cohort.

P1.17.71 Treatment Changes Over 12 Months of Observation for ALK and EGFR-Positive NSCLC - Results From an Real-World Study

B. King-kallimanis[1], K. Glynn[2], T. Chihuri[3], J. Feldman[4], Y. Diaz[5], J. Gibbard[5], U. Basu Roy[3]
[1]LUNGevity Foundation, Tarpon Springs/FL/USA ,[2]LUNGevity Foundation, Boston/MA/USA ,[3]LUNGevity Foundation, Chicago/IL/USA ,[4]EGFR Resisters, Deerfield/IL/USA ,[5]Oncogene Cancer Research, London/GB

Introduction: It is important to understand patterns of and impact of treatment changes in patients outside of the clinical trial setting. While most patients with ALK or EGFR-positive NSCLC may derive substantial benefit from their first-line treatment, a group of patients require treatment switch within one year of starting treatment. Here, we sought to investigate participant-reported treatment change and its impact on physical functioning (PF) and quality of life (QoL) at the time of treatment change in a longitudinal real-world study.

Methods: We analyzed data from LUNGevity Foundation's longitudinal study on the experiences of people living with lung cancer (Project PEER). In this analysis, we focus on people who reported stage IV ALK (n=63) or EGFR-positive (n=92) NSCLC with at least one follow-up assessment (n=152). We compare those who also reported a treatment change (n=56) (defined as change in medication or change in dose) at any time during the 12-month follow-up period to those who did not (n=96). Patient-reported outcomes (PROs) included EORTC QLQ-C30 domains of PF and general health (GH)/QoL, a patient-reported performance status (PS) and overall side effect bother single items.

Results: • More participants with EGFR-positive lung cancer (42%) reported a treatment change than ALK (29%). • For the 56 participants who reported change, there were a total of 121 changes as more than one change could be reported. The most common reason for a change was disease progression (45% of changes) followed by side effects (21%). 27% of changes involved a dose change prior to a treatment switch. • No difference was noted on baseline performance status, PF and GH/QoL between participants with a treatment change and those without. • Among those with EGFR-positive lung cancer and reporting a treatment change (n=34): o 14% rated their overall side effect bother as "severe"/"very severe", however, 32% self-reported their performance status to be equivalent of ECOG PS 2/3.o Median PF and GH/QoL were 6.6 and 17 points lower (worse) respectively at time of a change of treatment than their scores at baseline. Variability throughout was observed (PF Figure 1).
